Dr. Donald Macalister's recent lectures at the College of Physicians on "Antipyretics" have been, to some extent, complementary to the Gulstonian Lectures delivered by him last year at the same institution. In the latter he had intentionally passed over the treatment of fever. In his present course he did not propose, he said, to limit himself to the antipyretic drugs and their pharmacology, but would discuss rather the light thrown on the nature of fever by the means employed successfully for its treatment, and also the lessons in the treatment of fever which flowed from a right understanding of its nature. He briefly recalled the outlines of the theory he presented last year, and spoke of the nervous mechanisms of heat-loss or thermolysis, of heat-production or thermogenesis, and of heat-balance or thermotaxis. These mechanisms constituted the thermal nervous system, and were in an ascending order of complexity and of evolution. Fever was a dissolution, beginning with thermotaxis and extending to the inhibitory mechanism of thermogenesis; hyperpyrexia was a still deeper dissolution, and extended to thermolysis. The lecturer then went on to call attention to some recently acquired anatomical and physiological facts which had not, in his opinion, received as yet sufficient attention. Some valuable experiments on the physiology of thermolysis had been made recently by Dr. Masje, under Professor Eichhorst, of Zürich. These experiments involved high skill in physics and in mathematics, and had therefore possibly been overlooked. They related to the radiating power of the skin. Dr. Macalister said that probably sixty per cent. of the heat leaving the body did so by radiation. It had been assumed that this loss was regulated by the known physical laws of radiation. The physical law was that a hot body radiated less as its temperature fell. This, however, was not the physiological law. At the Zürich hospital, by the aid of an instrument of great delicacy and precision, on the principle of Langley's holometer, the true laws of skin radiation had been worked out. A part of the skin suddenly uncovered naturally became cooler, but it was found that its radiation increased steadily as the temperature fell until a certain limit was reached. Radiation was found to be more intense in men than in women, in boys than in girls, in young persons than in old, and in the vigorously healthy than in the feeble, or those convalescing from illness. There were reasons for believing that the radiating power of the skin, which depended upon its physical and chemical constitution, was subject to nervous control; what was apparently the most purely physical of all the thermolytic processes was thus not outside the domain of the thermal nervous system. I have referred to the abstruse nature of the researches of Dr. Masje. I may say, *en passant*, that in Dr. Donald Macalister the audience had a lecturer well fitted to interpret to them the results of experiments involving a knowledge of the higher branches of mathematics and physics. Dr. Macalister is not only a scientific and painstaking physician, but a mathematical scholar in no mean degree, having graduated at Cambridge as senior wrangler in the Mathematical Tripos of 1877. He then turned his attention to medicine, and having graduated in medicine also, became physician to Addenbrooke's Hospital, Cambridge, and Lecturer on Medicine at the University.

The lecturer then went on to speak of the connection between peripheral and central temperatures. Referring to the apparent lawlessness of surface temperatures as taken by any of the ordinary methods, he said that recent inquiries carried out at Zürich, under Professor Eichhorst, had shown that the difficulty lay chiefly in an erroneous method of procedure. When peripheral temperatures were taken continuously for eight or ten hours, the curves obtained consisted of two portions both in health and disease. During the first hour or two ("ambiguous stage") the temperature was highly irregular, and different from the central temperature. The second period ("continuous stage") was marked by much greater uniformity and by nearness to the central temperature; like the latter, it tended to be constant and stable. Some valuable contributions to the anatomy and physiology of the nervous system were then referred to by the lecturer. He said that new points (he would not call them centres) in the thermogenic tract had been made out by Ott and others in America, using the methods and working under the inspiration of Professor Wood. In the rabbit four points in the cerebral axis were known, the stimulation of which gave rise to increased heat-production, not merely rise of temperature. Two were at the anterior and median borders of the corpus striatum, one between that body and the thalamus, and a fourth at the anterior end of the thalamus. Dr. Hale White had, in part, verified the localization as regarded the anterior striate centre, and had made out that unilateral irritation gave rise to bilateral pyrexia. The question was then discussed of whether these points were on excitor or inhibitory tracts, and the experiments of Girard in Geneva, and Baginsky and Lehmann in Berlin, were adduced. They were apparently contradictory, but Dr. Macalister pointed out in detail how they might be reconciled.

In his second lecture, Dr. Macalister dealt with what he said might be termed the teleological pathology of fever. In all ages some had maintained, and the proposition was now being revived, that fever was not wholly nor in itself injurious. It was regarded as a wholesome reaction against a materies morbi, a manifestation of the vis medicatrix. Cohnheim had said that it might plausibly be maintained that in febrile heat we should recognize a sanative power, by which the body consumed and destroyed a virus it could not directly eliminate. Hilton Fagge was inclined to take a like view. After the long prevalence, especially on the Continent, of the idea that the dangers of fever were primarily due to the high temperature, and that to reduce the latter was the chief end of treatment, the reaction was remarkable. It was due partly to disappointment with the effects of vigorous antipyretic treatment on the course of the specific fevers. Another factor in the reaction was the growth of the germ theory. It had been maintained that the specific fevers were due to the intrusion into the body of certain microphytes, which engaged in a struggle for subsistence with the tissue-cells. Pyrexia might thus be regarded as a reaction brought about by natural selection to favor the latter in the struggle, and to hamper or disable the former. The result was, or should be, that the microphytes were overcome, consumed, and thus through the fever the body was restored to health. It was true that some of the best known microphytes were checked in their growth or multiplication by high temperatures, but such facts were not really relevant. A body temperature of 107° to 109° F., kept up for days or weeks, was too powerful a remedy. The body would be consumed before its parasite. A less direct explanation was suggested in a recent lecture by Von Ziemssen, viz., that the pyrexia so altered the constitution of the tissues that the microphytes no longer found in them a suitable soil and so perished. But against this was the fact that the exanthemata tended strongly to run a definite course, whether the fever were high or low. The lecturer then discussed the cases cited by Fagge and others, in which the febrile paroxysm seemed to have a destructive effect on the living virus of relapsing and intermittent fevers. These cases were shown to admit of a simpler explanation, one applicable to all the diseases attributed to micro-parasites. Like other living creatures, these parasites had a definite life-period which was independent of pyrexia, of antipyretic treatment, and of external influences. It had been shrewdly asked by Goldscheider, why, if pyrexial temperatures were not in themselves dangerous, they should in ordinary cases be confined within such narrow limits? Reverting to the question of evolution as bearing on the subject, Dr. Macalister remarked that the reasoning of the germ-theorists was two-edged, and might be turned against themselves. Were not the bacterial plants engaged in a struggle for existence? Might not the fever they induce be salutary to the bacteria? He would not lay stress on that argument. In concluding his lecture, he observed that high temperature in itself was not proven to be salutary, nor was it in itself the efficient cause of all the morbid phenomena commonly described as febrile.

Two figures of note have recently disappeared from the midst of us, viz., Dr. Harrington Tuke and Dr. Milner Fothergill. The former was an alienist physician of note, and practised as such for many years at the west end of London. He also, during the last forty-two years, had medical charge of a large lunatic asylum at Chiswick. He contributed to medical literature many papers on insanity and cognate subjects. Dr. Milner Fothergill is probably well known through his writings to many of your readers. He was indeed a voluminous writer, both of books and of papers in the periodical press. His style was easy and flowing, and helped greatly in gaining readers for him. Not, indeed, that he was deficient in originality, but the special charm of his writings lay in his style. If, at times, a want of exactitude might be detected and details omitted for the sake of effect, it was easy to condone trivial omissions when the bulk of what he wrote was so eminently interesting and instructive. As a profession we do not excel as *littérateurs*. It is therefore a pleasure to point to one who does us honor in that respect. Dr. Fothergill had long been an invalid, though he continued to practise as a physician till quite recently. He was extremely corpulent, but although his figure made him noteworthy wherever he appeared, he was very cheerful about his misfortune, and would make jokes at his own expense. He died only two days ago, aged forty-seven.

The Council of the College of Surgeons are, it appears, not to have their own way without further question. The night before last, in the House of Commons, Lord Randolph Churchill gave notice that he would on an early day move an address to Her Majesty the Queen, praying that a supplemental charter be not granted until a full inquiry has been made into the constitution of the College.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE MARRIAGE OF YOUNG PEOPLE WITH ORGANIC HEART-TROUBLES—ALCOHOLISM AND CRIMINALITY—EMOTIVE PHENOMENA IN HYPNOTISM.

PARIS, June 29, 1888.

THE physician is often consulted on the propriety of marriage of young persons of either sex affected with cardiac lesions. The question is rather a grave one to resolve and should not be lightly treated. According to some authors, all the lesions of the heart in women should be a barrier to their marriage. Professor Jaccoud is not so absolute in his opinion on that point, and he distinguishes two groups of lesions of the heart which should more particularly have an influence on the settlement of the question. In a lecture on the subject the author stated that, in the first group the valvular lesion, duly demonstrated by physical signs, has never produced any accidents. In these conditions, Dr. Jaccoud sees no valid reason to interdict the marriage, if the person interested desire it. In the second group, the lesion of the heart has already produced serious accidents. being confined more or less to the condition termed asystolic. Even then, there is no absolute rule. In a case like this, the physician must take into consideration the nature of the accidents caused anteriorly by the cardiopathy. If these accidents are pulmonary, he must be more severe than if it were simply an œdema or hepatic congestion. Moreover, he must consider how these accidents were borne by the patient, and how she recovered. One must also take into account the effect which the interdiction may produce on the person interested as to her desire or indifference to contract marriage. There is here a complex consideration, of which the non-medical elements should be taken into serious account. Finally, the conditions in which the woman would go through her pregnancy should be equally attended to. If she is obliged to work for her living, marriage in such case should be interdicted; if, on the contrary, she is in a position to avoid all fatigue and to rest as completely as it is necessary, she may be authorized to marry.

In a recent communication to the Academy of Medicine on alcoholism and criminality, M. Maramhat endeavored to establish the pernicious influence of alcohol on individuals and on society in general. In examining the history of three thousand condemned persons he found that, of vagabonds and beggars there were seventy-nine per cent. who were confirmed drunkards; that of assassins and incendiaries there were from fifty to fifty-seven per cent.; those convicted of indecent assault, fifty-three per cent.; thieves, swindlers, etc., seventy-one per cent., and, finally, in acts of violence on persons there were eighty-eight per cent. drunkards and seventy-nine per cent. in acts of violence on property. Among youths under twenty years of age, drunkards are nearly in as great number as adults, the difference being only ten per cent. The author observes that there is here an indication of the starting-point of the passion for drinking, and as of a hundred young persons not having as yet attained the age of twenty years, sixty-four per cent. are already given to drink, it is evident that it is on the side of the child by an education and by special measures that the evil must be attacked. The classification by departments, as given by M. Maramhat, confirms the assertions of the late Dr. Lunier on the great number of drunkards which exist in the departments where, owing to the absence of the cultivation of the vine, alcohols of industry are consumed in much greater quantity.

At a recent meeting of the Academy of Medicine, Dr. Dujardin-Beaumetz read the report of the commission charged to examine and verify the statements related by Dr. Luys in his essay "On the Experimental Solicitation of Emotive Phenomena in Subjects in a State of Hypnotism." The reading of this report gave rise to a discussion which promised to be most instructive, but I shall, for the present, only transcribe the last two paragraphs:

"Faithful to the task which was confided to the Commission, the members have thought that their mission was here terminated, and that in acknowledging the extreme good faith of Dr. Luys, it was sufficient for them to show that the effects produced by medicaments placed at a distance in hypnotizable subjects appeared to depend more on the caprices of fancy, and of the remembrance of the subject of experiment, than on the medicamentous substances contained in the tubes in this case." Hence the members of the Commission unanimously adopted as a conclusion the following resolution: "The Commission named by the Academy of Medicine to examine the facts advanced by Dr. Luys, at its meeting of August 30, 1887, on the subject of the action of medicaments at a distance on hypnotizable subjects, express the opinion that none of the effects established by the Commission were in relation to the nature of the substances experimented with, and that, consequently, neither therapeutics nor medical jurisprudence need take into account such effects." This decision is looked upon as a great blow to hypnotism; but Dr. Luys, who has been anxiously expected since March last to respond to the above judgment, has not yet presented himself at the Academy.

Apropos of hypnotism, the *Medical Press* has reproduced a letter addressed by Professor Charcot to Dr. Melotti, an Italian physician. In this letter, Dr. Charcot exposes the real dangers to which morality and health are subjected by the public exhibitions of hypnotism. The author states that "hypnotization is not as inoffensive as some would pretend it to be. The state of hypnotism so nearly approaches that of hysterical neurosis, that, in certain circumstances, it may, like this latter, become really contagious. If medicine, in the name of science and of art, has taken possession of hypnotism, it ought to retain it within the strict limits of its domain, to use it as a powerful therapeutic agent, and never to deliver it to profane hands, capable of abusing it to the detriment of the general health."

In his inaugural thesis for the doctorate, Dr. Renard, of Nancy, wrote on the "Parallel between the Operation of Cataract by Simple Extraction, and by Extraction combined with Iridectomy." The author makes the statement that the operation by extraction, according to the method of Von Graefe, after having been received with so much enthusiasm a quarter of a century ago, now counts very few partisans. It is the French method—that which is due to Daviel—which is again in favor. The author remarks that, thanks to antisepsis and to eserine, the same reproach cannot be applied to simple extraction as formerly. Extraction combined with iridectomy exposes to grave complications. Simple extraction has for advantage to leave to the eye its normal aspect, to give a better visual acuity, to attenuate the size of the circles of diffusion during the exercise of vision, to permit the patient to distinguish more easily, without changing glasses, the objects placed at different distances, to give to the eye operated on a greater tolerance for the variations of light, to less expose the organ to the dazzling of an intense light, also to erythropsia (vision in red). Extraction combined with iridectomy should be reserved for complicated cataracts. The author concludes that as many cases of success are obtained with Daviel's method as with that of Von Graefe.

The Douche as Affecting Blood-pressure.—Dr. Vishegorodski has published his researches on the effects of the general douche at different temperatures on the blood-pressure, pulse, respiration, and temperature. The experiments were conducted in a military hospital, the eleven subjects being hospital orderlies. The reservoir from which the water for the douches was supplied was about fifteen feet above the floor of the bath-room. From the reservoir two tubes, each about three-quarters of an inch in diameter, conveyed the water to the vicinity of the subject; one of these delivered the water in the form of rain; the other delivered three jets directed to the liver, the spleen, and the back. The duration of the douche was two minutes. The blood-pressure was estimated by means of Basch's sphygmo-manometer, an instrument which consists of an elastic pad filled with liquid placed over the radial artery, and communicating with a mercurial or aneroid manometer. Dr. Vishegorodski found that with douches of from 63° to 90° F. the blood-pressure was considerably increased, but that douches of from 100 to 114° F. diminished it. The increase of pressure in the former case was found to persist for some time, not returning to its normal amount for more than an hour after the douche. The variations in the blood-pressure occurred simultaneously with corresponding variations in the cardiac beats, the latter becoming slower as the blood-pressure increased and more rapid as it diminished. This appears to be contrary to the results obtained by Delmas, who, however, judged of the pressure merely by sphymographic observations. Douches of a little over 90° F. produced scarcely any effect on the blood pressure, the pulse, or the respiration.—*The Lancet.*

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 15 to July 21, 1888.

De Witt, Calvin, Major and Surgeon, U. S. Army. Leave of absence extended one month. S. O. 159, A. G. O., July 11, 1888.

Banister, William B., Lieutenant and Assistant Surgeon. Leave of absence extended twenty-seven days. S. O. 157, A. G. O., July 9, 1888.

Official List of Changes in the Medical Corps of the United States Navy for the week ending July 14, 1888.

Owens, Thomas, Assistant Surgeon. Detached from Naval Station, New London, and to Coast Survey Steamer Gedney.

Crandall, R. P., Assistant Surgeon. Detached from the U. S. S. Saratoga, and to the U. S. S. Galena.

Martin, William, Assistant Surgeon. Ordered to Marine Rendezvous, San Francisco, Cal., and to attend officers of the Navy and Marine Corps not otherwise provided with medical aid.

Auzal, E. W., Assistant Surgeon. Detached from duty at Marine Rendezvous, San Francisco, Cal., and special duty there, and ordered to the Naval Academy.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 14, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	15	1
Scarlet fever	91	14
Cerebro-spinal meningitis	5	4
Measles	217	19
Diphtheria	127	42
Small-pox	3	0
Yellow fever	0	0
Cholera	0	0

The Cancer Bacillus.—The recent alleged discovery by Scheurlen of a "cancer bacillus" has not received much confirmation as yet. Indeed, in this country the failure of Messrs. Ballance and Shattock, in their carefully conducted experiments, to obtain any such microbe by cultivation of morbid growths has sufficed to make us extremely sceptical of the results declared by Scheurlen. The subject has been again discussed in Germany, for at a recent meeting of the Berlin Clinical Society a paper was read by Dr. Emil Senger, in which much the same ground was traversed as that covered by the above observers. Dr. Senger pointed out that the arguments in favor of cancer being infectious were based upon the mode of its dissemination through the body, the occurrence of cases of acute miliary carcinoma, the supervention of cancer on chronic cutaneour irritation, and, less convincingly, upon the occasional occurrence of "cancer by contact." At the same time, the fact that the secondary growths reproduce the characters of the primary within tissues of wholly different nature formed a marked distinction from those infective tumors that are ascribed to the action of bacterial organisms. In tuberculosis and actinomycosis (he might have added syphilis) the tumor is composed of indifferent cells, which are homologous with the elements (connective tissue) in which they occur. In fact, there is no instance known of a bacterium giving rise to heteroplastic growths—*i.e.*, composed of cells dissimilar to those occurring at the seat of infection. The cancer microbe, if such there be, must then be intimately associated with the cancer cell or its nucleus, a relation which would therein differ from what is ordinarily believed to exist between the cell and the microbe. The problem is rendered more difficult from the fact that hitherto cancer has never been successfully inoculated upon the lower animals. We all know how the inoculability of tubercle was proved long before the bacillus tuberculosis was discovered; and the failure of such experiments with respect to cancer (which Dr. Senger himself has repeated with equal non-success), affords additional evidence of the difference between tubercle and cancer as regards their respective degrees of infectivity. It may be that the failures depend on the inability to select an appropriate locality in the body for inoculation of cancer, or to employ cancer of a special histological kind or in a special stage of growth, as being more virulent in the one than the other, or, what is very probable, upon the animals selected being insusceptible to cancer. These and other explanations may be proffered to explain the very limited infectivity that cancer seems to possess. As to Scheurlen's bacillus, Dr. Senger repeated the experiments upon which that discovery was based, making numerous cultures of portions of cancerous tumors upon various media (gelatine, agar, blood serum, and ascitic fluid), without obtaining a micro-organism which could be recognized as specific; and although in one instance he did encounter a bacillus having characters similar to those described by Scheurlen, he proved satisfactorily that this bacillus was due to the potato upon which the culture was made. He did not think the question would be solved until new methods of cultivation were introduced, and he discountenanced bacteriological study before the transmissibility of cancer was proved.—*The Lancet.*

Angioma of the Epiglottis causing Hæmoptysis.—Dr. Desvernine describes a case of repeated hemorrhage from the mouth occurring in a healthy man, aged fifty-three, the cause of which was for some time obscure. On making a laryngoscopic examination, an ovoid tumor measuring two centimetres by one was found attached by a peduncle to the laryngeal aspect of the epiglottis. The tumor appeared to be lobulated, and was of a violet color. From the history of the hemorrhages, taken together with the color and general appearance of the tumor, Dr. Desvernine diagnosed it as an angioma, and decided to remove it by means of the galvano-cautery. This was accomplished without difficulty, the pharynx and larynx having been previously anæsthetized by means of a strong solution of cocaine. An examination of the tumor showed it to be a pedunculated and encapsuled angioma. —*The Lancet.*

Complicated Operation on the Intestines.—Professor Hofmokl recently brought before a Vienna Medical society a moman, aged twenty-nine, from whom he had, owing to the presence of carcinoma, removed a part of the colon ascendens, the cæcum, and the appendix vermiformis. He immediately united the intestine and closed the abdominal wound. The operation which had recently been recommended for such cases consisted in the resection of the intestine, the application of an artificial anus, and the union of the resected parts of the intestine at a later period. As to the patient under consideration, she noticed, two years ago, the presence of a tumor in the right abdominal region. As the tumor was movable, the attending physician diagnosed a movable kidney, and directed the patient to wear a pelote. The pains from which the patient suffered, however, gradually increased, so that the pelote had to be removed. Disturbances of digestion and severe diarrhœa also supervened. The, patient on her admission into the clinic of Professor Hofmokl, was somewhat emaciated; her abdomen was non-distended, and a movable tumor of the size of a fist could be felt in the hypochondriac region.

The irrigation of water into the colon could not facilitate the diagnosis, as a stricture of the intestine was absent, the injected water finding its way through the diseased part. As the patient suffered from fever, and the tumor showed a high degree of mobility, it was suggested that they had either to do with a movable kidney or with carcinoma of the colon. The tumor was found to be covered with a part of the epiploon, and the mesocolon was rather long. A part of the colon, as well as the cæcum and the processus vermiformis, were removed, and were afterward closed with a threefold series of sutures. The temperature rose to 100.4° F. during the first days, and the patient passed at that time fetid and liquid stools. Injection of a solution of the salicylate of sodium removed the fetor at once. The patient speedily recovered, and was completely cured. The mesenteric glands were not enlarged, and the disease present was adeno-sarcoma.—*Medical Press.*

Summary of Recent Methods of Testing for Sugar.—1. *Fehling's Method Modified by Seegen.*—The urine is filtered through a thick layer of animal charcoal (of blood), which absorbs the whole of the sugar; the charcoal is washed out with distilled water, which dissolves out the sugar, which may be tested with Fehling's solution; traces of sugar will be found in the second, and even in the third and fourth washing. This method is mostly used by the chemists of Carlsbad.

2. *Penzoldt's Method.*—Some drops of a solution of acetate of lead, mixed with some drops of ammonia, are poured into a testing-tube half filled with urine. If sugar be present, the precipitate will be rose-colored; if not, white. This is a pretty good and sensitive test.

3. *Johnson's Method.*—Some drops of picric acid are added to the urine, which is then mixed with a solution of potash slightly heated. A light red color appears in normal urine; the presence of sugar makes the color deep red. As the difference between the two is only a difference in shade and not in color, the observer is naturally exposed to optical mistakes, a matter which impairs the value of the test. It can, nevertheless, be recommended for its other good qualities.

4. *E. Fischer's Method Modified by Jaksch.*—This method is highly to be recommended in every respect. It is based on the power of phenylhydrazine to unite with grape-sugar and form characteristic crystals. To a measuring beaker half full of water two drachms of hydrochloric phenylhydrazine and three of sodium acetate are added; the compound having been heated a little, the same quantity of urine is added, and placed in a vessel of boiling water for fifteen minutes; it is then quickly put in very cold water. After standing for some minutes a yellow sediment slowly falls, in which crystals of phenylglucosazon are always to be found if the least quantity of grape-sugar be present in the urine. These yellow crystals have the shape of long rods, terminating at each end in round balls or bunches.

5. *Molisch's Method.*—The recently invented double method of Molisch ([1] α napthol and [2] thymol, both with sulphuric acid) is worthy of mention, as it will detect the presence of even 0.0001 per cent. of grape-sugar; it is, however, entirely useless for our purpose, as it produces exactly the same reaction with cane-sugar, maltone, and all dissolved albuminates.—*British Medical Journal.*

To this should be added perhaps the best of all, viz., 6. *The Fermentation Test.*

Zittmann's Decoction in Syphilis is a preparation used considerably in Germany, and to some extent in this country. Dr. I. Tscherniavsky, of Warsaw says that he "does not entertain any doubt that its action must be attributed to its powerful diaphoretic and laxative properties, which cause a considerable increase and acceleration of the systemic metabolism, and, in virtue of this, promote rapid resorption and elimination of syphilitic products, the effect being intensified by a specific remedial action of mercury present in the decoction (*fortius*)."

Dr. Idelson, of Berne, commenting on this in the *Provincial Medical Journal*, says: "Modern practitioners are far from being unanimous in their opinions in regard to the therapeutic value of the old remedy under consideration. Thus, Professor Zeisse, of Vienna, thinks that all decoctions generally manifest but an exceedingly trifling influence on the involution of the morbid process. Professor E. L. Lanceraux, of Paris, similarly relegates Zittmann's decoction to the category of insignificant auxiliary resources." Meanwhile, Professor Veniamin M. Tarnovsky, of St. Petersburg, in his translation of Lanceraux's text-book, adduces (p. 713) a striking instance of extremely severe syphilis cured by the remedy after all other means in vogue have failed. Again, Professor Alexander H. G. Gay, of Kazan, most decidedly raises his authoritative voice in favor of the decoction: "The action of Zittmann's decoction," he says, in his "Course of Venereal Disease" (third edition, 1888, p. 555), "is sometimes strikingly beneficial. Under its appropriate administration the patients show a rapid improvement, regain a good appetite and a healthy complexion, and commence to increase in their weight, while their seemingly intractable ulcers, which have been previously resisting all possible means, become cleaner and generally more healthy, and soon heal altogether." The use of the remedy is said to be indicated mainly in late forms of syphilis, especially in patients gravely exhausted, both by the disease itself (ulcers) and a prolonged (and possibly irregular, or wrong) treatment. Dr. Gay advises to use the strong decoction (*d. fortius*), commencing with ten or twelve fluid ounces (divided into three equal portions, two of which are to be taken warm in the morning, in the course of fifteen or twenty minutes, and the third in the evening), and ascending gradually to one and a half or two fluid pounds, provided the patient tolerates it well. The patient's diet is to be light, easily digestible, and nutritious. The treatment must not last less than one or two months. The beneficial action of the preparation is ascribed by Dr. Gay partly to its favorable influence on the patient's digestion and nutrition, and partly to its containing mercury. In what chemical state mercury is present therein, remains yet undetermined. At all events, it exists in the decoction in some combination which is easily tolerated by the stomach, and rapidly passes into the blood current, since Vajda and Paschkis were able to detect mercury in the patient's urine on the second day of the use of Zittmann's remedy. That the latter does contain mercury has been proved beyond any doubt also by Schneider and Zantl, who, on one side, observed mercurial stomatitis after the use of the decoction alone, and, on the other, obtained mercury in a direct way from the decoction. Thus, according to Zantl, 720 grammes of the strong decoction contain 0.0125 gramme of mercury in the shape of corrosive sublimate. Professor Kaposi, of Vienna, also finds (*Sprimon's Meditzina in* 1886, vol. ii., p. 989) Zittmann's decoction "a very effective means in late forms of syphilis."

The Sensitive Rectum.—Painful hysterical spasm of the rectum is a most common neurosis, says Dr. Wm. Godell in *The Medical Standard.* Another rectal neurosis is the "jealous" rectum, which puts a veto on social intercourse. One lady was in a perfectly comfortable condition until she put on her bonnet, when this unruly organ would remonstrate audibly and continue until the unfortunate possessor would be compelled to take off her bonnet and make up her mind to stay home. After this everything would become quiet. Another lady always began to have an evacuation from the bowels as soon as she received a letter from her husband, and was obliged to delay reading it until the rectal demands had been satisfied. A third would soil her bed after any violent mental emotion. All were kept prisoners at home, and had to abandon social intercourse. A third form is "follicular colitis," or "membranous enteritis," which is often a hysterical neurosis.

THE ETIOLOGY AND PATHOLOGY OF INCREASED BODILY HEAT IN RELATION TO DISEASE AND THE USE OF ANTIPYRETICS.[1]

BY WILLIAM HENRY PORTER, M.D.,

PROFESSOR OF CLINICAL MEDICINE AND PATHOLOGY IN THE NEW YORK POST GRADUATE MEDICAL SCHOOL AND HOSPITAL.

MR. PRESIDENT AND GENTLEMEN: We find a large number of articles in our medical journals devoted to the subjects of increased body-heat as recorded by the clinical thermometer. We likewise find a still larger number of articles lauding the efficiency of the various new antipyretics as they are announced. At the same time, there is a conspicuous absence of articles devoted to the study of the etiological factors which excite the increased bodily temperature.

The first question naturally suggested is, What is a true conception of increased bodily heat? Does it simply mean that the body is too hot, as recorded by the clinical thermometer, and that this increased heat must be subdued or death will result? Or is this increased temperature to be looked upon as a single symptom only, which indicates a grave disturbance of the chemico-physiological processes of the animal economy, a continued disturbance of which process must necessarily be followed by a continued fever, or a continued rise in the temperature?

It appears to me that too much stress has been laid upon the high temperature *per se*, as recorded by the thermometer, and far too little attention devoted to the physiological disturbances.

The numerous medical books and standard works on medicine give very little satisfactory information in regard to the etiology and pathology of fever, for fever by them is only treated of in connection with the various diseases in which it exists as a symptom, and even then the discussion of the subject is purely from a clinical stand-point. Everyone undoubtedly appreciates the fact that the various causes of increased bodily heat cannot be accurately followed step by step from cause to effect. But a careful study of the laws which govern the normal production, with the pathological changes that occur in all those diseases in which an abnormally high temperature has been a characteristic symptom, tends to throw much light upon this obscure subject; a condition which for a long time has been treated empirically, and with little or no thought of the disturbed chemico-physiological and pathological laws governing the same.

Physiologically speaking, animal heat is produced by the motor forces or the kinetic energy being converted into heat; that is to say, the molecular friction of the microscopic elements of the body. The largest amount of heat, however, is probably produced by the transformation of the chemical elements of the food, which are endowed with a large amount of potential energy that is given off in the form of heat as they are being converted into more stable products having little or no energy. At the same time the physiological economy is so constructed that while it is producing heat it can both store up and excrete heat. These phenomena are chiefly effected by the condition of the skin and other excretory organs, and in this way the body-temperature is normally maintained at a mean standard, namely, that of 37.6° C., or 98.5° F. Further than this, some have claimed that there exists a special cerebral heat-centre, which has for its function the property of maintaining this uniform standard of body-heat. But as yet it has not been located with any degree of positiveness, and, so long as we have no accurate knowledge of its location, or of any drugs acting upon it, no practical value can be derived from its existence. That the chemico-physiological production, storage, and excretion of heat are without any connection with the nervous mechanism is impossible to maintain, but what the working of that connection is remains an unsolved problem.

From what has already been said it appears that under all circumstances the increased body-heat above the normal standard can be attributed to one of two causes: First, to an increase in the molecular friction of the body without a disturbance of the chemico-physiological processes, and one in which the body-nutrition is still maintained at the normal standard. A typical illustration of this class was reported by Dr. J. W. Teal[1] at the Clinical Society of London, in which a temperature ranging from 108° F. to 122° F., and upward, had been maintained for a period of nearly nine weeks. Numerous cases of a similar nature have been reported. These cases plainly demonstrate the fact that the body can withstand a very high temperature and yet suffer no serious damage. For this reason it is clear that we should not consider the increased heat *per se* as the damaging element, and it further points to the necessity of discriminating between the two different kinds of increased bodily temperature when treating the same.

The second form of increased body-heat is due to a disturbance of the chemico-physiological processes, with a decrease in the nutritive activity of the protoplasmic elements of the body; this change in nutrition being primarily most marked in the liver, kidneys, heart, and visceral organs, until finally every tissue in the body becomes impaired. With this there is an increased storage, and a decreased excretion of heat. These conditions will also increase the frictional irritation, which now acts as one of the minor elements in producing the rise in temperature. In this light the increased body-heat, as recorded by the clinical thermometer, is only a symptom, pointing in the one case to an increased molecular friction and storage of heat without impairment of nutrition. In the other case, to a grave disturbance of the chemico-physiological processes, with marked impairment of nutrition, increased storage, and decreased radiation of heat, and associated with extensive retrograde changes in the body, which are most marked in the visceral organs.

The question naturally raised by this conception of the subject is, What is the cause of the increased temperature? In all the acute and infectious diseases there is unquestionably something introduced into the system, either a micro-organism, a ptomaine, or some impalpable substance. The first effect of this poison, if we may term it such, upon the system is to disturb the normal functional activity of the liver. This assertion is supported by clinical, pathological, and experimental evidence. Clinically we know that the liver is at fault by the following symptoms: The marked tendency to nausea and vomiting of "bilious" matter, primary constipation, and clay-colored stools.

---

[1] Read, by invitation, before the Ontario Medical Association, at Toronto, June 9, 1887.

[1] Medical Times and Gazette, March 20, 1875.

The urine, also, is decreased in quantity, high colored, strongly acid, and often loaded with uric acid and urates, both indicating incomplete or partial tissue-metabolism.

Pathologically we know that the liver is among, if not the first organ to suffer, for the hepatic cells in all acute diseases become enlarged, softened, and abnormally granular, and ultimately their protoplasm undergoes a complete granular and fatty metamorphosis, the extent of these retrograde changes depending upon the severity and duration of the chemico-physiological disturbances.

It has further been proven by the experimental observations upon animals, by Dr. G. Pisenti, that there is a diminution in the quantity and quality of bile secreted directly in proportion to the intensity of the fever. He, however, considered the change in the biliary flow as purely functional, and not resulting from any structural change in the liver-cells. But it is hardly possible to conceive of an abnormal glandular secretion without some abnormality in the protoplasmic elements composing the organ implicated. Further than this, careful pathological study and microscopic examination of the protoplasm of the liver-cells, in all the diseases in which an increased temperature was a marked clinical feature, has shown a granular and fatty metamorphosis, and argues strongly against the purely functional view, and supports an organic change as the cause of the disturbed biliary secretion. Following the retrograde changes in the liver, the kidneys, heart, and various organs of the body undergo a similar granular and fatty metamorphosis, either in the order of their physiological importance or their nutritive condition, at the time of the attack.

As a natural sequence of these observations it becomes apparent that whatever the etiological factor may be, its first deleterious effects are to produce a disturbance of the normal activity of the liver, which is manifested by a diminution in the quantity and quality of bile secreted. This at first functional disturbance is speedily followed by a marked granular, and later a true fatty, metamorphosis of the liver-cells.

As a result of this functional and organic disturbance of the hepatic function, the intestines are deprived of their requisite quantity of biliary secretion, which acts as their normal disinfectant and peristaltic excitant; consequently the intestinal digestion and absorption is incompletely performed. The nutritive materials absorbed and taken to the liver being in a very imperfect state of transformation, they likewise carry with them considerable effete material, which has resulted from the increased decomposition constantly going on in the intestinal tract. This further interferes with the hepatic function and decreases the nutritive supply of the liver-cells, and has a marked tendency to cause a progressive metamorphosis of their protoplasm.

Under these circumstances the work to be performed by the liver is greatly increased, its biliary secretion and nutritive supply decreased, and its epithelial protoplasm impaired. Naturally in this condition the nutritive substances leaving the liver for general distribution to the tissues of the body are in an imperfect and irritating condition, and the general nutrition is imperfectly accomplished. The effete material now resulting from tissue-waste that is to be eliminated is unusually large and very irritating. The nutrition of the excretory organs is diminished, and their power of excreting heat, especially that of the skin, is impaired, while the storage of heat is increased by the inability of the kidneys to rid the system of the rapidly accumulating effete matter. There is now an abnormally large amount of effete and unduly irritating material constantly circulating in the blood, which, together with the original poison and the increased intestinal irritation, causes an increased production and storage of heat, with a decreased excretion of the same, and explains the high temperature. At the same time the cerebral centres are kept in a state of irritation, which accounts for many of the nervous manifestations associated with the increased temperature.

If the skin, kidneys, alimentary tract, and excretory organs can eliminate this effete and unduly irritating material as rapidly as it is produced, then there will be little or no retrograde change in the protoplasmic elements of the body, and the temperature will rise but little, if any, above the normal standard. But when the opposite is true, the temperature will continue to rise until the fatal end is reached, or until the vital centres are suddenly paralyzed and the patient passes into a state of collapse with a falling or subnormal temperature.

Taking this view of the subject, the chemico-physiological disturbances and parenchymatous changes of the visceral organs are the cause of, and not the result of, the increased bodily heat.

Assuming that this functional and organic derangement of the liver and excretory organs is the chief pathological factor in producing and maintaining an abnormally high temperature—that the original poison of the disease is the chief etiological factor—we are in a position to study the comparative merits of the various antipyretic remedies, and ascertain if they have a tendency to interrupt these abnormal physiological processes, and aid nature in reestablishing the normal standard.

First, is quinine a general antipyretic? That quinine is a positive antidote to the malarial miasm introduced into the system no one can deny. It destroys or removes from the system the exciting cause of the disease, after which nature immediately restores the functional activity of the liver and excretory organs, when the normal temperature is regained and maintained. But in all the cases where there is no malarial miasmatic poison associated with the infectious disease, quinine has little or no effect in reducing the temperature. Many individuals, however, are all the time more or less poisoned with malarial miasm, and in them the development of any acute or infectious disease enables the malarial poison to become a more active agent and one of the factors in exciting an increase in the bodily temperature. In these instances the quinine antidotes whatever influence the malarial element may have in exciting and maintaining the body-heat above the normal standard. But when the cases are carefully studied those in which the malarial element is absent are found to be unaffected by the administration of cinchona or its alkaloids. Consequently we are not justified in regarding quinine, in any form, as a general antipyretic. From this peculiar and specific property of quinine in malarial pyrexia Professor Andrew H. Smith, of New York, has suggested that, in all infectious diseases in which there is an abnormal rise in temperature, a different and specific cause exists, and for each there may be a special antipyretic, as quinine is for malaria. If we could isolate each separate cause, and discover the drug or remedy that would antidote it, then this theory would be fully confirmed.

Second. Salicylic acid acts as an antipyretic by its property to decrease fermentation in the alimentary canal, thus shutting out one of the elements which help in destroying the nutritive and functional activity of the liver, and which, secondarily, cause a general disturbance of the system at large. It also increases the heat-excreting power of the body by its pronounced diaphoretic action. This naturally favors the surface radiation and prevents to a certain degree any increased storage of heat by the system, and consequently the abnormally high temperature is lowered.

Third. We will consider a group of so-called antipyretics which includes antipyrine, antifebrine, thallin, kearnin, resorcin, etc.

They will be treated in common, as their action is quite similar. What their physiological actions are in reducing temperature has not been satisfactorily demonstrated. Experimental study, however, shows that in large doses they produce a rapid and marked parenchymatous metamorphosis of the liver and kidneys, which is followed by albumin and casts in the urine. They are also thought to have a direct depressing effect upon the medullary and spinal centres. This being true, is not their antipyretic action due to their causing a further increase in the functional and organic metamorphosis of the protoplasmic elements of the body, which disturbs still more the physiological processes of the liver, kidneys, and excretory organs, and thus causes a greater accumulation of effete and toxic matter in the blood, until the accumulation becomes so large that a state of general depression is produced, which throws the system into a condition strongly simulating that known as collapse, during which the temperature falls? As the system recovers from the shock, if it does, this large amount of waste material continues to increase the irritation and general disturbance to the system, and causes the temperature to rise to a higher degree than that attained prior to the administration of the drug. This view finds considerable support in the clinical course of the diseases in which these drugs have been given, and still more in the pathological conditions found at the necropsies.

Clinically it has been frequently noted that the patient died suddenly from heart-failure after a dose from this group of remedies. Another very noticeable fact is the very high temperature that follows their administration, patients frequently dying with a rapidly rising temperature, which almost invariably succeeds the fall produced by their action. Before the introduction of this group, death with a temperature above 105° or 107° F. was a rare occurrence, while since their introduction death with the temperature rapidly rising to 108° F., 109° F., or 110° F., and higher, is quite common.

Many a hospital interne has asked, are not the high temperatures of to-day due to the new and free use of these coal-tar products?

Pathologically we find at the present time more marked and destructive parenchymatous changes in the liver and kidneys than was the case before the introduction and use of this group. In many instances the examination of the liver and kidneys has revealed a condition of granular and fatty metamorphosis equally as bad as that found in acute yellow atrophy of the liver, or in connection with acute phosphorus-poisoning.

Experimental research with this group has taught us that their full or toxic action is to produce a parenchymatous transformation of the liver and kidneys, with the development of albumin and casts in the urine. If they are capable of producing this effect in normal organs, is it not reasonable to suppose that in diseased conditions, when the general tendency is to parenchymatous changes, they will produce this same transformation more rapidly and in much smaller doses?

Dr. Frederico Vananzio, after a clinical study of the use of antipyrine in scarlet fever, reaches the following conclusions:

1. Antipyrine certainly reduces the temperature in scarlet fever for a length of time and to an extent which varies with the dose and individual; but the fever, on the cessation of the drug, returns with renewed intensity, even when by the careful and diligent use of the remedy it has been possible to suppress it for many hours in succession.

2. During the hypothermia produced by the administration of antipyrine, no appreciable improvement, either subjective or objective, is manifested by the patient, aside from the simple reduction of the fever.

Indeed, the ordinary syndromes and complications of the disease are neither prevented nor modified. In the toxic form, when it is desirable to re-enforce the "cardiovascular tone," the antipyrine does not in the least oppose the advance of the collapse.

3. Antipyrine prolongs rather than shortens the duration of the disease.

4. In some it produces cerebral congestion, persistent vomiting, and prostration.

Dr. Jacubowitsch, after using antipyrine in various diseases in children, comes to the following conclusions: Antipyrine lowers the temperature in all cases, but to a very slight degree in healthy children. The amount of the fall did not always depend on the dose. The temperature did not remain at the lowest point for more than twenty hours. The greatest fall occurred about midnight, after which the temperature gradually rose. In healthy children even large doses failed to lower the temperature to the same extent as in the feverish; young children take large doses well for from one to two days. In most of the cases the quantity of urine was diminished to the extent of nearly one-half; it was concentrated, and the specific gravity was increased. The quantity of urea, uric acid, sodium chloride, phosphoric and sulphuric acid was notably diminished during the use of antipyrine. Forty-eight hours after the last dose the daily quantity of all these urinary constituents was greater than before the drug was given. The author feels some hesitation in recommending the use of antipyrine in fever cases, because, in spite of its antipyretic power, it could not safely be used for any length of time if the remarkable retention of the products of oxidization is confirmed.

Professor Ehrlich reports a case (*Münchener med. Wochenschr.*, No. 8.) which ended fatally under repeated progressive doses, namely, 0.08 up to 0.58 gramme (one and one-quarter to nine grains), of thallin tartrate. The necropsy showed the lesions of typhoid fever in the healing stage, cardiac hypertrophy and dilatation, and hemorrhagic infarctions of the renal papillæ, the last mentioned being, as shown by experiment, a characteristic sign of thallin-poisoning. He further assumes that the danger may be completely avoided by fixing the minimum dose for hourly administration at 0.2 gramme (three grains) of the tartrate of thallin.

Professor William H. Draper, in a paper read before the Academy of Medicine of New York, reported twenty cases treated with antipyrine, with a death-rate of five in twenty, or a mortality of twenty five-per cent.

Dr. Götze, in the *Berlin. klin. Wochenschr.* of March 9, 1885, gives as the results of his experience with antipyrine the following conclusions: That in no case has he observed the course of the disease shortened by the use of antipyrine, and that in the severe general infection not only the fever but the remaining symptoms fail to be influenced by the drug.

Professor Ehrlich, in the *Münch. med. Woehenschr.*, No. 47, commenting upon the action of thallin in typhoid fever, makes the following statement: Of twenty-eight cases treated by bathing, the average stay in the hospital was thirty-seven days; of seven cases treated by thallin (minimum doses) the duration of treatment was forty-seven days, and cases on a scale of progressive doses thirty-eight days.

The result of cases treated with antifebrine is even less favorable.

The preceding observations necessitate the following conclusions and queries:

First. That this group of antipyretics will lower temperature, but at the same time they will cause a retardation of the excretory functions of the body, and a retention of the waste, or effete products of the system.

Second. They do not modify the intensity nor shorten the duration of the disease, but tend to prolong the symptoms.

Third. The fall of temperature is only temporary at best, and is generally followed by a higher temperature than that existing prior to their administration.

Fourth. Their use gives a high death-rate, and in some instances they appear to be the direct exciting cause of the fatal issue.

Summing up this experimental, clinical, and pathological proof naturally leads one to argue strongly against the use of any of this group of drugs as antipyretic remedies; and raises the question, Are they in any sense, from a physiological and pathological basis, true and safe antipyretics?

Again, have they increased or decreased the mortality in connection with the acute infectious and contagious diseases? Unless it can be absolutely proved that they decrease mortality, and tend to prolong life, we are not justified in using them, even if they do lower bodily temperature.

Although many articles have appeared praising the usefulness of this class of remedies, we have the above plain facts in opposition to their use. This much can be said, it has not been proven that they in any way antidote the poison, neither have they shortened the duration of the diseases in which they have been administered, or decreased the mortality, while there is much proof to the contrary.

They may possibly decrease intestinal fermentation to a slight degree, and thus aid in cutting off one source of irritation; but if, following this, they cause increased parenchymatous metamorphosis, with retention of the excrementitious products, and impaired nutrition in general, they certainly destroy the physiological vitality of the body, which more than overbalances any good effect that can be credited to their action.

Fourth. The cold bath or pack deserves a word. The physiologists teach that in case the body-heat has been increased by active exercise, which necessitates greater oxidization, exposures to cold or draughts are dangerous, for they tend to arrest the function of the skin, and cause a retention of the excretory products of the body, which gives rise to the condition commonly termed a cold, while in some instances grave visceral disturbances or true inflammatory processes are developed.

When the human body is suffering from a fever the increased heat is the result of this increased work of chemico-physiological oxidization, and the greatest excretory activity is necessary to rid the system of the rapidly accumulating excrementitious products. To subject the surface of the body at this time to the cold pack or bath arrests the functional activity of the skin and tends to produce internal congestion, and causes increased excretory work for the kidneys and intestines, which is often followed by increased parenchymatous changes in the liver and kidneys, followed by the sudden appearance of albumin and casts in the urine, uræmic toxæmia, and death. There are, of course, a certain number who can subject themselves to cold after violent physical exercise without apparent ill effects; likewise some patients can withstand the ill effects of the cold pack or bath without apparent damage and ultimately throw off the effects of both the disease and the treatment. This, however, is no guarantee that the majority can. It is further a well-known fact that many practitioners have abandoned the cold pack and bath, because observation has taught them that under their influence the mortality was unusually high.

The following is often noted after their use: Instead of the temperature remaining down after their application, it will again rapidly rise, the cerebral symptoms will become more active, albumin and casts will appear in the urine, and death follow from uræmia in a few hours.

All cold packs ultimately act as hot packs, and in this way excite the skin to increased excretory activity, provided the patient has the inherent vitality to rally from the primary shock and physiological disturbance. In this way we have an explanation for the favorable cases credited to the use of severe cold applications.

Fifth. Diaphoretics: Of them all it may be said that they are true physiological antipyretics, for they assist the skin to excrete more heat by keeping a larger volume of blood near the surface of the body, and thus keep up a more active evaporation. They also aid in the elimination of the effete material from the system.

Sixth. Diuretics, like diaphoretics, are positive antipyretics, aiding as they do the system to rid itself of one of the chief elements in maintaining the abnormally high temperature. The kidneys being the chief organs by which the system excretes the waste material resulting from proteid metabolism, special attention should be devoted to these organs from the very inception of every acute or infectious disease, as their nutrition is apt to be impaired, while at the same time the work required of them is increased, until finally they are unable to accomplish their task. The urine becomes more scanty, high colored, strongly acid, of a high specific gravity, and often loaded with uric acid, urates, etc. This change in the urine is soon followed by albumin and casts, uræmic or toxic symptoms are developed, which are made evident by an aggravation of all the symptoms of the disease, but especially the cerebral, and death speedily ensues.

Seventh. Alcohol also acts as a serviceable antipyretic by diminishing body-oxidization, and at the time supplying to the system a hydrocarbon that it can utilize. In this way more water is produced, diaphoresis and diuresis increased, and the heat-radiating power augmented. At the same time it improves the general nutritive condition of the body and aids in preventing heart-failure.

Eighth. Sponging with tepid water and alcohol is one of our most efficient means for reducing temperature, provided it is properly employed. It causes a rapid excretion of heat, and acts as a stimuli to the skin and renders it more active—one great object to be obtained.

In bathing the sick one rule should be rigidly enforced. After sponging a portion of the body the nurse should rub the skin of that part perfectly dry with the bare hands before another portion is bathed. There is nothing more uncomfortable than to be left wet and clammy. On the other hand, nothing is more refreshing and soothing to a patient than such a bath, provided the skin is dried in the way suggested.

Ninth. But the remedy which strikes strongest at one of the main sources of the increased temperature is the pure ox bile, or the fel bovis inspissatum. The administration of bile causes the milk to curdle in fine flakes and be more perfectly digested. It prevents intestinal decomposition and stimulates a gentle peristalsis, which favors the capillary circulation of the intestine and increases the rapidity of absorption. The fel bovis also increases the perfection of the intestinal digestion, which, together with a more rapid circulation and peristalsis, causes absorption to be most perfectly accomplished. At the same time these favorable conditions decrease the amount of effete and irritating substances that can be drawn up into the system with the nutritious elements. As a result the liver receives a much larger quantity of pure nutritive substances and a smaller amount of irritating and deleterious matter; consequently the work required of the hepatic cells is lessened, and the nutritive pabulum reaching the system at large is better in quality, and the nutrition in general is kept at a higher standard. The resulting excretory products are necessarily more perfectly formed and are less irritating to the excretory organs.

We now find the abnormal heat-producing power reduced to the minimum, less stored up, and the excretory organs better able to eliminate whatever increased heat is developed.

In this way a nearer approach to the normal standard is maintained, the original poison is given less chance to injure the system, and it is easily and rapidly eliminated.

These statements are especially true in connection with typhoid fever, and it has been a noticeable fact, both in my own cases and those of others who have followed this line of treatment, that the patients had less tympanites, less cerebral disturbances, and the temperature was maintained at a moderately low degree throughout the disease. Albumin and casts in the urine were rarely found, and when they did appear they were in small quantities.

In pneumonia, where the temperature is largely due to continued absorption of the rapidly liquefying inflammatory exudation, increased storage and decreased radiation of heat, the fel bovis inspissatum does not reduce the temperature to so marked an extent. But in so far as it improves digestion, absorption, and assimilation in general, it decreases the storage power and increases the excretion of heat, and thus brings down the temperature to a certain degree. Also by improving nutrition it increases the eliminating power of the excretory organs and often prevents a fatal renal complication or a sudden failure of the heart's action. The accomplishment of even this is of great advantage in all pyrexial states.

"The Strathmore," Broadway and Fifty-second Street.

A CASE OF CEREBRAL TUMOR.

Epileptiform Attacks for Two Years—Temporary Aphasia and Right Hemiparesis—Absence of Severe Headache and Vomiting—Tumor between the Fourth (Lobulus Fusiformis) and Fifth Occipito-temporal Convolutions and the Posterior Horn of the Lateral Ventricle—Secondary Changes in the Temporal Lobe and the Insula.

By ROBERT T. EDES, M.D.,

WASHINGTON, D. C.

A lady, aged fifty-eight, had been deaf from girlhood. For some time previous to 1886 she had had severe attacks of what she called neuralgia in the head, which had disappeared, or nearly so, after the use of massage. She thought herself of a gouty constitution, and considered these neuralgias or headaches to be connected with that diathesis, and to have nothing in particular to do with her later trouble.

After the summer of 1886 she had only occasional headaches, which, though appearing somewhat severe at the time, she made light of afterward, and sometimes spoke as if she hardly knew what headache was. They seemed to be in the forehead.

On December 12, 1886, she had an attack of epileptiform character and considerable severity, which was repeated at longer or shorter intervals through the succeeding year until I saw her, and until she died. As these attacks did not vary essentially in symptoms, although somewhat in severity, they may be described once for all.

There was, first, a period of unconsciousness, the face becoming livid, then of mental confusion with amnesic aphasia, involving not only the names of things, but the words to express action and relation (chiefly, but not solely, nouns). This condition lasted one or more hours. With these greater attacks, though, I think, increasing in frequency as the more severe ones grew more rare, there were also slighter attacks of incoherency and aphasia lasting a few moments and occurring quite frequently. The exact amount of mental confusion in these could not be ascertained, owing to her deafness, her reticence, and her dislike to being watched. She was fully aware of these lesser attacks herself, and was annoyed by them. She said she had short and slight ones which no one noticed but herself. Her appearance during them was not much changed; of the severer fits she knew but little, but was aware that something had been the matter.

On February 22, 1887, she was heard to be breathing heavily, and found with her arms twitching and unable to talk intelligibly. Before the end of my visit she could make part of a sentence, but not finish it. The lower facial nerve on the right side was distinctly paralyzed, but not the upper. Her servant stated that on former occasions, when she had fallen, it had been upon the right side. This attack was followed by some headache; she complained of doors banging and of the nurse walking heavily. On the 25th it was noted, "she speaks well and intelligence is perfect." The headaches did not seem to have made much impression on her memory, although she says she was never subject to them, a statement not sustained by the earlier part of the history. In March she had an attack, beginning with a cry, which did not last a great while.

During the spring of 1887 she had many of the slight vertiginous attacks, but not many of the more severe ones.

May 23d.—Attack of aphasia lasting some minutes. No other symptoms except dilatation of the pupils. She complained of pain in the back of the neck.

During the summer she was away, returning in October, and considering herself much better, although she said she had not had a comfortable or agreeable summer.

On October 13th she had a short but severe fit, the convulsions occurring on the right side. She was forgetful, and repeated questions; thought that she had just returned and had not seen me since. This condition lasted a number of hours. During the next month, on one occasion, when out walking, she seemed dazed and her hand shook.

About the middle of December I received a somewhat peculiar note from her, with the address repeated in an awkward way, and the writing unnecessarily crowded and uneven, but no misspelling or wrong word. When I called to see her she spoke of the note as written in a hurry, and seemed to have an idea that it was not quite right. Another one, some days later, although incoherent and vague in places, informed me clearly of her wish, and showed that she retained a full recollection of our conversation some hours previously. Her notes and memoranda on household and business matters about this time were much confused by the omission and wrong combination of words, and at times unintelligible.

The aphasia became constant and much more marked; she could not get the words for things, nor form phrases to express her ideas. She seemed to realize this fully, and to be much annoyed, though apparently not alarmed, by it. She constantly forgot words in conversation, and would say with impatient expression and gestures, "Why! you know what I mean." There was no indistinctness of pronunciation. This condition was attributed by her to the medicine she was taking (iodide of potassium and bromide of sodium), and she expressed great gratification at having it stopped, although I could not make out whether what pleased her most was giving up the medicine or the cessation of the attacks of vertigo (or petit mal), of which she had much less for some time.

The following circumstance will serve to illustrate the form of aphasia, which seemed to be purely amnesic: In order to test her, I told her that a lady, a former townswoman, whose name I purposely omitted, had come to reside in a house in the neighborhood. She seemed to understand me, and to be annoyed that she could not tell me the name. She walked into the next room, got the right card from the table, read the name to me with perfect distinctness, and said the lady and her daughter had called on her a short time previously, and added that she (the patient) had always known her. As I was going away she said "hot" for "cold," and indicated by gestures and detached words that she thought I was imprudent to be without an overcoat, the name of which garment, however, she could not recall.

This aphasia increased without changing its character. The paresis of the right side became distinct and permanent, though never complete. The patient dropped things from her right hand; this hand was noticed to tremble, but she continued to use it for gesticulation, especially when she could not get the word she wanted.

During her walks she began to act more strangely, appearing forgetful, taking the wrong street, dropping things without noticing it, and once or twice making a sudden run after someone in the street. She became wilful and uncontrollable. At the table she acted strangely, forgetting the usual proprieties, as to which she was ordinarily very punctilious, using the wrong dishes, trying to cut meat with a spoon, etc. On the day before her death she walked out, but was very difficult to manage. It was noticed that she constantly tended to turn to the right, and on stepping on to the curbstone her right foot was raised with difficulty.

On the morning of January 11th she could not take her accustomed beef-tea, but went through the motions with her fingers as if she had held, and was using, a spoon, and said she had had enough. When I saw her she was very drowsy, supporting her head on her right hand. This hand shook much, the other a little. Her stupor rapidly deepened and she died at 6 P.M. Her pulse became quite slow, but continued to beat strongly some moments after she had apparently ceased to breathe. There were no convulsions. A few hours before her death the right pupil was widely dilated, and the left of medium size.

During her sickness the urine was repeatedly examined without important results. At times there was considerable swelling of the feet. On more than one occasion there was said to be a great tumefaction of the lips and face, which, however, owing to her peculiarities of disposition, I was not allowed to see. She used to say that she had always been subject to swellings of the kind on various parts of her body, and seemed to regard the swelling of her feet as of the same character with them, and of no great importance. The swelling of the feet, however, was distinctly anasarcous, while the others I considered, from the description, to have been of the kind recently called angioparalytic œdema. The condition of the eyes has not been hitherto alluded to. The fundus was examined in the summer of 1886, and again in February, 1887, with negative results. Unfortunately this was the last examination. There was no defect of vision except myopia. She used to read the paper every evening, and no such phenomenon as hemianopsia could have escaped her own observation.

As to more general symptoms, it may be said that there were none sufficiently decisive to be of value. When she first came under my care she complained of weakness, but was always in the habit of walking out. At first she carried a cane, but afterward discarded it. During her illness she gave up drawing and the reading of foreign languages, of which she had formerly been fond, and read little but the newspaper. There was no marked change of disposition, and the only appearance of a delusion was when she told me circumstantially about a friend who was coming to live with her, when, in reality, all the arrangement that had been made was her having requested the lady to do so.

At the autopsy, which was confined to the head, the scalp and calvaria were found moderately rich in blood, the dura tense but otherwise normal, the convolutions flattened and dry. On opening the fissure of Sylvius, on the left side, the convolutions of the island of Reil seemed to be swollen and pale, apparently œdematous, as if some growth lay immediately underneath. The whole anterior of the extremity of the temporal lobe was softened.

On the lower surface of the occipito-temporal lobe a small spot of discoloration was found, connected with a tumor lying in the interior of the lobe and covered with a thin layer of cerebral substance. It was situated chiefly between the fourth occipito-temporal convolution, which, with the two neighboring convolutions, was distended over it, and the posterior horn of the lateral ventricle, into the cavity of which it had not actually made its way, although very nearly doing so. It was about four centimetres in diameter, from upward and inward toward downward and outward, three thick, and about three antero-posteriorly. It was of soft and somewhat friable consistence, yellow and reddish in color, as if some small hemorrhages had taken place into its substance. It was quite clearly defined from the surrounding tissue, though not having any distinct capsule. In structure it was a spindle-celled sarcoma.

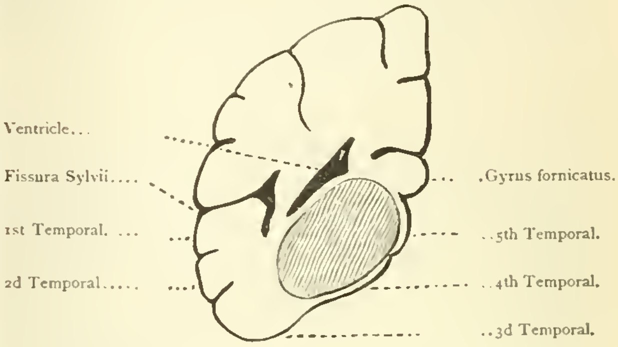
The position is more accurately defined by the accompanying diagrams, of which one represents a section corresponding very nearly to Dalton's Plate XVII., that is, a little posterior to the extremity of the corpus callosum, and anterior to the point of the cuneus. It extended backward from this section perhaps one centimetre or more, and forward so that the point just appeared in another section corresponding to Dalton's Plate XIV., a distance of a centimetre and a half.

In the other diagram is represented, on the lower surface of the cerebrum, the position of the tumor, which was only a short distance below the surface, covered with a thin layer of the normal color except in one dark-brown spot.

The softening portion of the temporal lobe was not examined microscopically except in the fresh condition, when it seemed to contain nothing but the normal elements of brain tissue.

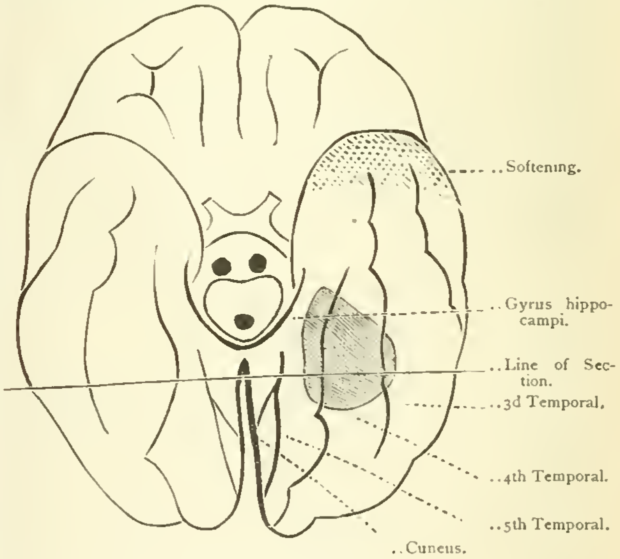
Of a piece comprehending the third frontal convolution and the island of Reil, on the left side, sections were very kindly made for me by Dr. W. M. Gray, of the Army Medical Museum, with his usual skill. The island showed, in comparison with the frontal, a proliferation of the elements of the neuroglia in the two outer layers, and possibly in the deeper ones.

In the deeper layers the nerve-cells were surrounded by a larger space between themselves and the neuroglia than on the third frontal, or rather there were a larger number of cells so surrounded. Both of the above-named convolutions showed these changes more markedly, as compared with a section from a frontal convolution of the opposite hemisphere. I was not sure that I could make out any alteration in the cells themselves.



Section of Left Lobe of Cerebrum at Line marked in the other Diagram.

These changes would perhaps indicate little more than an œdema, somewhat dissociating the deeper elements, with a frequently recurring congestion, giving rise to proliferation of the connective tissue in the periphery. Tumors in the region where this one was found are rare, and I have been able to find not a single one which corresponds very nearly to it. Tumors of the occipital lobe are not so rare; but by far the greater number of them are situated in the space between the ventricle and convexity, or in the convex cortex itself. A similar statement may be made as to the temporal convolutions.



Inferior Surface of Cerebrum.

The following cases concern tumors not very remote from the location of that described :

Burney-Yeo (*Brain*, 1878, vol. i., p. 273): A lady, aged sixty-nine. General loss of power, chiefly in lower part of body; right foot lifted with difficulty and slowly;

toe dragged; right hand a little weaker; mental faculties obscured; difficulty in finding words; memory impaired; severe headache in left side and back of head; double optic neuritis.

There was a large oblong glioma, the size of a goose's egg, weighing nearly six ounces, chiefly in the white substance of the posterior lobe, not extending beyond the posterior half of the hemisphere, nor to upper surface so as to reach convolutions, nor to interior surface so as to interfere with structures at base or floor of ventricles.

Langmore ("Trans. Path. Soc. Lond.," 1851–52, iii., p. 240): For four months frequent headache; pains down right arm in paroxysms; last two days delirium in attacks, but consciousness perfect between them; no previous paralysis.

Tumor in the interior portion of posterior lobe of the right side, the size of a pullet's egg, soft, embedded in the substance, and approaching within few lines of the surface.

Mitchell (*Edinb. Med. Journ.*, 1883–84, xxix., 430): Sudden unconsciousness; no convulsion; another attack, then dementia; sensory and motor functions impaired on left side.

Hemorrhages in left corpus striatum. Under the posterior part of the floor of the left lateral ventricle a tumor, three-fourths of an inch in diameter, globular, firm, and resistant; in right corpus striatum old hemorrhages.

I have thought this case worth putting on record as a contribution to cerebral localization, on account of the unusual situation of the primary lesion, and have to remark upon the following points:

Hemiparesis is so common a symptom with cerebral tumors in a great number of situations that it has little value for regional diagnosis. It may probably be produced by any tumor of sufficient size to exercise, either directly or by secondary congestion, a general compression of one hemisphere, as well as of the motor region alone. In such a case as this, where, for a long period, it was present only for a few hours, or usually only a few minutes at a time after a fit, it is to be attributed with much the most probability to the pressure of a temporary congestion which rapidly subsided. At a later period its permanent presence to a slight degree might have coincided either with the changes in the insula and its subjacent ganglia, or to the increase in general pressure.

As to the epileptiform attacks, not of a strictly localized character, a similar remark may be made. The present case might have been considered as supporting the view that connects epilepsy with invasion of the gyrus hippocampi, had it not been that an epileptiform attack was the earliest distinct symptom, while the gyrus hippocampi was barely touched by the anterior extremity of the tumor, and was hence, presumably, only recently invaded.

Another point of interest is the absence of hemianopsia, which, according to recent observation, seems to be quite clearly connected with lesions of a part of the occipital lobe, that is, the cuneus, or a part of the convexity or white matter corresponding thereto. Here it was probably the unusually low situation of the tumor, clearing the cuneus and the fibres which pass forward from it, or from the convexity, that prevented it from interfering with vision.

Taste and smell were unfortunately not carefully tested. The softened condition of the point of the temporal lobe might have given rise to abolition or diminution of the acuteness of these senses.

The aphasia, of a purely amnesic character, both as regards speaking and writing, and having so little to do with any motor disturbance, is interesting in connection with the limitation of the lesion of the motor region to the island of Reil. The third frontal convolution, which contains the centres for the movements of the lips and tongue, as in articulation, was, to the naked eye, apparently free from any lesion, and showing only rather doubtful ones under the microscope. It is, however, not going far to assume that the loss of memory for words was connected not with the lesion of these convolutions alone, but with a more widespread and less defined pressure effect.

The most definite studies of aphasia are naturally those which involve the connection of a sensory *im*pression—sight, hearing, or touch—with a motor *ex*pression—speaking or writing—and they have not as yet enabled us to locate memory, or stored up impressions, as distinguished from those immediately present.

The slight amount of headache during the time that the disease was actively progressing is a noticeable and important point in diagnosis, since so much stress is usually and correctly laid upon severe and localized headache to prove the presence of a cerebral tumor. Digestive disturbances, also, with the exception of a somewhat diminished appetite at various times, were conspicuous by their absence.

THE RELATION OF SPASMODIC ASTHMA TO CHRONIC HYPERTROPHIC RHINITIS.

By J. E. SCHADLE, M.D.,

ST. PAUL, MINN.

It is my desire in the presentation of this subject to invite especially the attention of the general practitioner to an infrequent form of asthma, which, it would seem, is still left to the specialist for recognition.

There is, without doubt, an intimate connection between spasmodic asthma and a chronic thickening of the mucous membrane covering the posterior portions of the inferior turbinated bodies and the septum narium immediately opposite.

It is to this especial etiological feature of the affection that I want to draw attention.

Four illustrative cases will be given, proving the correctness of the statement that an hypertrophy of the parts mentioned contributes in a great measure to the development of this form of asthma.

But before entering into a discussion of this fact it may be important to briefly review the theories advanced regarding the mechanism of spasmodic asthma when due to the presence of nasal polypi.

Since Voltolini made known his remarkable observation that polypi of the nose are a contributory factor to the production of reflex asthmatic symptoms, more recent writers have noted the same phenomenon. As to how a polypus in the nasal fossæ gives rise to paroxysms of dyspnœa, there is still, among authors, a difference of opinion.

On the one hand, it is presumed that its presence in a nasal cavity produces a stenosis, whereby a perfect interchange of the gases of the lungs is interfered with and asthma results. On the other hand, it is maintained, by authority equally eminent, that the polypus comes in contact with a sensitive part of the intranasal mucous membrane, sets up an irritation, followed by congestion and engorgement of the cavernous tissue, and creates by reflex action symptoms of difficult breathing.

The latter theory appears correct when it is remembered that certain portions of the membrane lining the nasal cavities are richly endowed with sensitive nervous filaments coming from the trigeminus, whose centre lies in close proximity to that of the vagus in the floor of the fourth ventricle, between which centres there undoubtedly exists an intimate sympathetic relation. If this physiological statement be true, then there is little difficulty in understanding how an irritant, when introduced into the nose, or generated therein by a diseased condition, can superinduce paroxysms of the disease in one asthmatically inclined.

The practical experiments of Mackenzie, revealing and establishing the existence of intranasal sensitive areas, are certainly invaluable in forming a reliable basis from which a minute and accurate study of nasal reflexes can be made.

According to his description, he found that the areas occupy a position on the mucous membrane clothing the posterior third of the inferior turbinated bodies and the septum narium directly opposite. He states that by irritating an area with a probe, or any other foreign substance, reflex phenomena follow, such as cough, sneezing, or dyspnœa ("Wood's Reference Handbook," vol. v.). I myself have observed the same truth enunciated by Mackenzie, when examining patients whose organization was of the nervous kind.

If, then, an irritant introduced from without is applied to one of the so-called sensitive spots, and gives expression to a phenomenon whose nature is entirely reflex, is it not reasonable to believe that a morbid process embracing an area, such as is the case, for example, of chronic hypertrophy of the mucous membrane, can in like manner produce a similar effect?

The pathological change of the tissues having gone on at an indefinite rate, in time alters the nervous as well as the vascular supply of the part. The individual in whose nasal passages such a change occurs, and on whose constitution the asthmatic predisposition is indelibly impressed, becomes, I believe, a fertile subject for a full development of symptomatic asthma.

I apprehend, further, that there are not a few cases of reflex asthma whose cause is seated in an intranasal affection when no other cause is manifest.

Dr. Clinton Wagner, of New York City, in his book on "Diseases of the Nose," refers to chronic hypertrophic rhinitis as a cause of asthma. He reports a case in which a cure was performed by a direction of appropriate treatment to the nasal disease. Dr. Wagner is not specific in his remarks with respect to the locality of the hypertrophy. He does not state what part of the mucous membrane had undergone a hypertrophic change during the progress of the rhinal disorder of his patient.

Woaks, in his excellent work—"Post-nasal Catarrh"—goes so far as to say, "there can be no doubt that some forms of chronic asthma have their origin in post-nasal affections, and are cured when these are got rid of." The following typical cases of nasal asthma came under my notice and treatment more than a year ago:

CASE I.—Mrs. L——, aged forty-years, the mother of three children, consulted me concerning violent paroxysms of asthma, from which she had been an intense sufferer for more than five years. During the first three years of her affliction the spells came on at irregular intervals. But for two years prior to consulting me they were marked distinctly by an entirely nocturnal appearance, occurring principally awhile after midnight, and as frequently as once in twenty-four hours. When an attack was unusually severe, it was a common thing for her the day following to be utterly unfitted to attend to the cares of her household. Atmospheric changes exerted an influence in regulating the severity of the seizures.

The family history indicated a decidedly neurotic temperament, the asthmatic tendency having prevailed among her antecedents. A physical examination of the chest showed no signs of lung disease. There was a slight bronchitis; a cough, too, accompanied the violent attacks of difficult breathing. The heart's action was normal; digestion good; bowels regular; uterine and urinary functions natural. The nervous system was sensitive and easily excited. A rhinoscopic examination revealed, anteriorly, the nasal cavities to be in a reasonably healthy condition; posteriorly, there were brought into view two large masses of hypertrophic mucous membrane arising from the posterior extremities of the inferior turbinated bodies and extending into the post-nasal space. On account of the great size of the growths the posterior nares were completely obstructed. In consequence of the stenosis thus produced, respiration was performed entirely through the mouth. The parts diseased were quite sensitive; a slight touch of the probe induced dyspnœa. Explaining to my patient the nature and situation of the hypertrophies, and also telling her that in my opinion they were solely at the bottom of her trouble, she willingly consented to an operation. Using a Jarvis cold wire-snare, I removed them at one sitting. The result was satisfactory; an immediate subsidence of the asthmatic tendency and a restoration of free nasal respiration took place. No trace of the disease has since appeared. Her general health, too, has improved in every way.

The last two years of her illness having been characterized by intensity of suffering, she was reduced in general health, anæmia and loss of flesh being conspicuous.

CASE II.—John M——, drug clerk, aged eighteen years, forms the subject of my second case. He complained of periodic attacks of asthma, appearing at longer or shorter intervals, and confining him to his room for several days at a time. The day he visited me he was just recovering from a bad attack. Aside from his asthmatic trouble he seemed in good health. There were no evidences present leading to the belief that his asthma was of bronchitic, peptic, or cardiac origin. On examining the posterior part of his nasal cavities, I discovered on the end of each inferior turbinated body a large growth of redundant tissue impinging against the septum and producing partial closure, which rendered nasal respiration quite difficult. I cut them both off with the cold snare. He at once experienced relief and a perfect cure followed.

CASE III.—Mrs. M——, aged fifty-five years, mother of John M——, came to see me regarding treatment for herself soon after her son's recovery. The commencement of her sickness dated back many years, paroxysms of asthma occurring periodically. Loud wheezing was a pronounced symptom when in the midst of a seizure. The suffering she endured was considerable, breathing being difficult and labored. Post-nasal inspection revealed an excessive thickening of the mucous membrane clothing each side of the septum narium. The redundant tissue was immense, and extended almost entirely across the posterior opening of each cavity to the turbinated body immediately opposite. When the parts were irritated a reflex effect occurred. The turbinated structures, as far as could be determined, were in a normal condition. I used the galvano-cautery to destroy the hypertrophy, employing the flat knife at a cherry-red heat. Three sittings, ten days apart, were necessary to effect complete destruction. No other measures were instituted in the management of her case. No symptoms of the malady have since appeared, and she has been in the enjoyment of good health ever since the last application of the cautery was made.

I have repeated these three cases for whatever interest and information from a clinical point of view they may contain. They certainly fortify the opinions of a few other observers in the fact that there is a *rhinal*, as well as a "bronchitic," a "peptic," or a "cardiac" cause of spasmodic asthma. In them, too, we find demonstrated the truth that it is necessary for that portion of the nasal mucous membrane engaged in a pathological process leading to an hypertrophy to include a sensitive area in order to produce reflex asthma.

In a personal communication to the writer, Dr. John N. Mackenzie, of Baltimore, relates a significant case strongly substantiating the view expressed above. By his permission I quote the case as follows:

"A man consulted me for violent attacks of asthma which compelled him to give up work entirely. Irritation of the sensitive area invariably produced an attack. He had two large posterior hypertrophies, both of which I removed with the cold wire-snare. *At each revolution of the nut and tightening of the wire he was seized with a violent paroxysm, so threatening that I was fearful that the operation would have to be suspended.* [Italics are his.] Seeing, however, that he came out of each attack with safety, I screwed the loop slowly home at long intervals and finally cut through the masses. Relief was immediate, and that night he slept without his asthma for the first time in several years. No other treatment was used beyond the ordinary spray. Two years or more have passed and the patient has not returned.

"This is, I think," he continues, "a fine case of so-called nasal asthma."

104 EAST THIRD STREET.

A SYNOPSIS OF TREATMENT IN TWENTY-SIX CASES OF PNEUMONIA OCCURRING CONSECUTIVELY IN A MISCELLANEOUS PRACTICE.

By HARRIS FISCHER, M.D.,

EASTMAN, GA.

No. 1. Negro laborer, aged forty, spare habit, general health indifferent; seizure abrupt and violent; prolonged chill followed by high fever and severe pain in the left side, with copious bloody expectoration. Croupous pneumonia.

Treatment.—Hot mush poultices, with oleum terebinth, applied to the painful part, with a hypodermic of morphia sulphas $\frac{1}{4}$ gr. Quinia sulphas, gr. v. to viij., every four hours during entire sickness. Tinct. aconiti rad., gtt. ij., every two hours. Carb. ammonia, gr. iij., every two hours. At night, usually, he had also $\frac{1}{4}$ gr. morphia sulphate, and if there was much elevation of temperature, antifebrine, gr. v. Convalescent in fourteen days.

No. 2. Mulatto boy, six years of age. Catarrhal pneumonia; began with catarrhal fever and diarrhœa; has been sick several days. When first seen had intense pain right side, much aggravated during the daily exacerbation; fever 103° F.; some mucous râles and hacking cough. Percussion signs negative; sputa, occasionally coughed up, confirms the diagnosis.

Treatment.—The same as No. 1, with appropriate reduction in dosage. Convalescent at tenth daily visit.

N.B.—In these two cases a troublesome typhoidal diarrhœa required the following every four hours:

℞. Sub. nit. bismuth	gr. v.
Oleum terebinth	gtt. v.
Emulsion gum acacia	q. s.,

with paregoric for boy and morphine for the man every six hours. Wine, whiskey, beef-tea, and milk throughout the cases.

No. 3. Mulatto boy, seven years of age. Croupous pneumonia, right side; sick four days when first seen.

Treatment.—The same, substantially, as No. 2. Bowels loose, but not obstinately so. Pleuritic pain persistent, and not completely relieved by treatment. I applied a blister on the fifth day of attendance. Sulphate quinia was given in five-grain doses, when the temperature was as high as 103° F. in the afternoon, and in smaller doses when the average pyrexia was lower. Convalescent one week from first visit.

No. 4. Negro girl, five years of age. Catarrhal pneumonia; highest temperature reached 104° F.

Treatment.—Poultice of mush and turpentine. Comp. tinct. opii. camph., every six hours. Quinia sulphas., gr. iv., every four hours. Tinct. aconiti rad., gt. j. Carb. ammonia, gr. ij., Water, q. s. S.—Every two hours.

This case (No. 4), as all the others, received a dose of antifebrine or antipyrine at bedtime, if the opiate seemed not sufficient to procure rest, or if there was a temperature noticeable at that time. Convalescent in five days.

No. 5. Twelve years of age; sister to No. 4. Case very much the same. Range of fever a little higher.

Treatment.—The same, with slight increase in the dosage. Convalescent in five days.

No. 6. Stout white child, male, four years of age. Sick three days when first seen. Catarrhal pneumonia.

No. 7. Brother to No. 6. Catarrhal pneumonia.

Treatment.—Mush poultices greased with lard next to the body. Tinct. opii, or paregoric, every six hours. The main treatment was quinia sulphas, gr. iij. to v., every four hours. Tinct. aconiti rad., gt. ss. to j., and carb. ammonia, gr. ij. to iij., every two hours. Convalescence, in both cases, tenth day.

No. 8. Stout country girl, white, aged eighteen.

No. 9. Sister of No. 8; more delicate, aged sixteen. These sisters nursed two preceding cases. Were taken with the same characteristic catarrhal prodroma, and developed in their turn unmistakable catarrhal pneumonia. They had for treatment the same as Nos. 6 and 7, with proper increase in dosage. The pleuritic pain was more intense, and hypodermics of morphine were used, with antifebrine, gr. v. to viij. per orem, for relief. Notwithstanding these girls took quinine in doses of gr. viij. every four hours much of the time, the temperature frequently reached 104° or 105° F. Antifebrine or antipyrine were used in this emergency, and sometimes morphine, and always with signal relief. They both had blisters. Recovery in eight days.

No. 10. Anæmic white girl, aged eight. Catarrhal pneumonia. Same treatment, with modified dose. Less pleuritic pain. Temperature, though high, did not seem to distress this girl so much; though she had a dose of paregoric or tinct. opii at bedtime, and sometimes antipyrine. Convalescent in five days.

No. 11. Precocious white boy, aged eight. Croupous pneumonia, third attack. Diagnostic points emphatic.

Treatment.—Mush and turpentine poultice. Paregoric to procure rest. Antifebrine when fever is 103° F. or more. Daily prescription, quinia sulphate, gr. v. S.—Every four hours.

℞. Carb. ammonia	gr. ij.
Tinct. aconiti rad	gt. j.
Water	q. s.

S.—Every two hours.

Diet—eggs, milk, whiskey. Convalescent in five days.

No. 12. White man, aged sixty-five; frail habit; history of twenty years' hard drinking; abstinent last five years. History of chronic intermittent fever four years; exempt for last five years. Has had several severe surgical injuries. Croupous pneumonia. Attacks sudden and violent, right side; seen early; reaction very imperfect.

Treatment.—Sulph. morph., gr. $\frac{1}{4}$, hypodermatically. Mush and turpentine poultices; later on, blister. Quinia sulphas, gr. v. to viij., every four hours.

℞. Carb. ammonia	gr. iv.
Tinct. aconiti rad	gtt. ij.
Water	q. s.

S.—Every two hours.

Third day responds to treatment well. Takes milk and whiskey freely. Expectoration abundant and easy. Distress is intense when pyrexia shows 103° F., and much relieved by antifebrine, gr. v. Fifth day case seems well in hand. Makes ineffectual efforts to stool; has had no evacuation in two days, and takes an aperient dose of calomel. Very copious typhoid-looking motions produced, with threatened heart-failure.

℞. Bis. sub. nit	gr. x.
Oleum terebinth	gtt. v.
Morph. sulph	gr. $\frac{1}{4}$,

in emulsion of acacia for diarrhœa, with whiskey, digitalis, and beef-tea to meet the cardiac depression. Patient rallied well. Now appears heavy; slightly delirious. Seventh day—expectoration, still easy, assumes a bright yellow tinge, with offensive breath. Then large dark evacuations, and an easy death on the eighth day.

No. 13. Married white woman, aged thirty-five years, mother of six children. Environment exceptionally bad. Sick three days. Pleuro-pneumonia. Passing the house was called in. Case desperate. Respiration rapid and jerky. Pulse 120, feeble.

Treatment.—Mush and turpentine poultice. Hypodermic of morphine.

℞. Carb. ammonia	gr. iv.
Tinct. digitalis	gtt. v.
Water	q. s.

S.—Every two hours.

Quinia sulphas, gr. vj., every four hours. As I was hurriedly leaving, husband informed me that she had missed two months and now had a moderate flow. Half teaspoonful of fl. ext. ergot was given in one dose. The environment absolutely forbade any manual examination or appliance for relief of this complication. Patient had profuse uterine hemorrhage following day, and died.

No. 14. Infirm woman, with history of asthmatic trouble, aged seventy-five years. Came several miles on a very cold day to take charge of the household just bereaved. Day following seized with violent pleuro-pneumonia. Seen at once.

Treatment.—Quinine, whiskey, and carb. ammonia in large and frequent doses. Hot mush and turpentine poultices, with opiates cautiously given, to procure rest and assuage pain. This was the main course of treatment, which resulted in recovery in fourteen days.

No. 15. Married white woman; has two children. Appears strong, although has occasional intermittent fever, contracted recently in Flordia. Pleuro-pneumonia. Has been sick six days. Remarkable tympanitic resonance of the entire affected left side.

No. 16. Father to No. 15. Cases, excepting the tympanites, wonderfully similar. Aged forty-eight years. General health bad. Pleuro-pneumonia. The advent of these cases was sudden, violent, and intensely distressing.

Treatment.—Mush and turpentine poultices. Later on blisters. Hypodermics of morphine when pleuritic pain was very severe. Quinia sulphas, gr. v. to viij., every four hours.

℞. Carb. ammonia	gr. iij. to v.
Tinct. aconiti rad	gtt. ij.
Water	q. s.

S.—Every two hours.

Dry cups, with tumblers, to back part of chest. Diet —whiskey, milk, eggs, beef-extract, and wine.

These cases were very severe, and for the pleuritic distress during exacerbation required various expedients. Morphine hypodermics, with antifebrine, met these indications best. At the end of the third week they each had morning temperatures nearly normal, appetite slightly improved; evening temperature 102 to 104° F.; profuse expectoration, abundant moist râles all over affected side, apex and all, with exhausting night-sweats and marked emaciation. At this period, also, No. 15 developed a large scrofulous abscess of the elbow-joint. Her brother died at fourteen of cervical scrofula. Her father (No. 16) at this period, while in the same general condition, was threatened with hepatic abscess. The consumptive tendency being well established they both now received the following treatment: Scott's emulsion, milk and whiskey, t.i.d., with rich kitchen diet. Aromatic sulph. acid and belladonna for night-sweats, and quinia sulphas, gr. viij., every four hours. Three weeks later they came out of their bedrooms, and finally made a perfect recovery on this last prescription.

No. 17. Negro woman, aged forty, mother of six children. Croupous pneumonia.

Treatment.—Quinine, carb. ammonia, comp. p. ipecac. et opii brought her to recovery in eight days.

No. 18. Negro man, age thirty-five. Treatment the same, with blister on the fifth day; morphine and antifebrine at night. Convalescent in fourteen days.

No. 19. White boy, aged thirteen. Croupous pneumonia.

Treatment.—Quinia sulphas, carb. ammonia. tinct. aconiti rad. Poultices at first, blisters later; antifebrine to procure sleep and reduce temperature. Recovery in eight days. Visited five days.

No. 20. Delicate white boy, aged six years. Croupous pneumonia, right side.

Treatment.—Sulphate quinia, gr. v., every four hours.

R. Tinct. aconiti rad	gt. j.
Carb. ammonia,	gr. ij.
Water	q. s.

S.—Every two hours.

Antifebrine, gr. v., was given every six hours for four days before sweating appeared. Convalescence was established in one week. Appetite and strength slowly returned in course of another week.

No. 21. Vigorous white girl, aged eight. Croupous pneumonia; physical signs very marked. This child expectorates.

Treatment.—Quinine, carb. ammonia, opiates, and poultices. Defervescence and recovery abrupt on fifth day.

No. 22. White, married, mother of ten children, aged forty-five. Croupous pneumonia.

Treatment.—Poultices in early stages, blisters later. Heavy dosing with quinine all the time in bed. Moderate continual use of aconite and carb. ammonia. Recovery in eight days.

No. 23. White female child, daughter of No. 22. Catarrhal pneumonia following measles. Quinia sulphas, gr. v., every four hours; tinct. aconiti, gt. j.; carb. ammonia, gr. ij. S.—Every two hours in water. Recovery in eight days.

No. 24. White boy, aged eight, brother of No. 23. Catarrhal pneumonia following measles. Treatment same as No. 23, only doses larger. In these two cases the quinine was given on some days of temperature 104° F. every two hours. Convalescent at the fifth daily visit.

No. 25. Stout laboring man, aged fifty five. Opium habit. Croupous pneumonia. Had a severe chill, followed by pain in right side and copious bloody expectoration. Temperature 100° F.

Treatment.—Quinia sulphas, gr. v., every four hours. Carb. ammonia, gr. iij., every two hours. Poultice to seat of pain. Recovery in five days.

No. 26. Athletic negro man, aged thirty. Croupous pneumonia.

Treatment.—Tr. aconiti rad., gtt. ij., every two hours. Hot mush and turpentine poultices over affected lung. Quinia sulphas, gr. viij., every four hours. Carb. ammonia, gr. iv., every two hours. Fifth day of attendance daily exacerbation increasing. Temperature at noon daily is 104 F., with great distress to patient. Increase the dosage of quinine at this hour to gr. xv. Apply tumbler dry cups to back over affected lung. Convalescent in ten days.

A detail of these cases exhibits the fact that, under the circumstances, the resources of the remedial art could hardly have done better, at least in point of ultimate recovery. The case of No. 12, who had full attention, from the day of attack made a wonderful fight, but with such a history, at such an age, it would have been a refutation of medical science if he had recovered. No. 13 was cited because her case was one of the twenty-six taken as they came up in ordinary practice, but truly she could scarcely be said to have had attention at all. The environment in the other cases was good, bad, and indifferent; and much more of the two latter than the first. Only one of them was seen more than once daily. Some of them not so often. The diagnosis was palpable and emphatic. Any possible case of capillary bronchitis was excluded.

Why produce this list of cases, and a treatment which has at least no novelty in it? Well, this synopsis shows, first, how "statistics are misleading." The reader sees the statement that, for instance, in this report, with this treatment, there was a mortality of two in twenty-six, or nearly eight in one hundred cases. It goes out that to this extent remedial effort failed and death resulted because of its inefficiency. When we know the facts we realize that there was no failure, and medication did all that it should be expected to do. Again it is urged that the too entire abandonment of venesection in the relief of pneumonia has changed the death-rate figures adversely. Now, according to the views of the bleeders, the chances are, in ordinary practice, that you will not see more than one in twenty cases early enough for the practice of that radical treatment. I saw only one of these twenty-six cases within six hours of the attack. This case was the old man—a physical wreck—No. 12. The last case, No. 26, was a model in physique for venesection, but his case had run on several days before I saw him, and was in its initiative distinctly malarial. Then, if blood-letting—given a proper case for its exhibition—could do no more than quinine and carb. ammonia, aided by an occasional dose of antifebrine, on the other hand, how much harm might come of it if one failed in that nice discretion in the when, and the how much, to use it. Once at least I have known a free blood-letting abort a pneumonia. More than once I have known a well-marked case getting well in twenty-four hours without it. In this argument I recognize the fact that there is no allowance for want of skill. Still, with this in view, I hold that he who bleeds to abort pneumonia must do it with a bold hand, or it is folly to do it at all. Such a one is like a general who puts in his whole force in one grand onslaught; if he succeeds, well and good, but if the pathological changes do not disperse, alas, for him, where are his reserves?

Ever and anon this must be the hapless luck of the doctor who bleeds for pneumonia.

I wish to emphasize another fact not yet mentioned. Ten of these cases occurring under circumstances so unusual, without history of exposure to bad weather or rigor of climate, and in groups, with other facts I have not space to mention, is well calculated to impress one that they were etiologically germinal and infectious. This, with the happy effect of giving quinine unceasingly, and in double doses when the pyrexia was distressing, all corroborates the present drift of scientific medicine, and from the standpoint of statistics even rebukes the idea of *going back* to venesection.

Progress of Medical Science.

THE INEFFICIENCY OF ZALESKI'S CHEMICAL LUNG TEST.—Dr. Blumenstock has published some observations on Dr. Zaleski's proposed chemical lung test, which depends on the larger quantity of blood, and therefore of iron, in lungs that have breathed than in those that have not. Only seven cases were examined by Dr. Zaleski, and the difference between the iron in the two classes of cases was not very great, and might well have been less if a more numerous series of experiments had been made. Apart from this and those faults of the method which Dr. Zaleski himself has admitted, there are, according to Dr. Blumenstock, the following objections to consider from the point of view of criminal investigations: 1. It is necessary to subject the whole of the lungs to a chemical analysis which would prevent other examinations being resorted to—as, for instance, by incisions; and a very useful means of diagnosis is thus cut off. 2. Zaleski in his method starts with the assumption that lungs which have not yet breathed contain less iron than those which have already performed their functions. But in the cases of most stillborn children, the lungs make respiratory attempts during birth, when the placental respiration ceases, and meconium, sebaceous matters, etc., get into the air-passages, death by asphyxia resulting. According to the theory of Donders, the lungs of those who die by drowning or asphyxia contain more blood when the occlusion of the respiratory passages takes place after expiration than in cases where this occurs at the end of inspiration; also the less liquid is taken into the lungs the more blood is found in them. Consequently, we find in such children, besides general venous stasis, the lungs, although free from air, are yet very hyperæmic, and ecchymoses usually exist in the pleura. Therefore, Zaleski's test could only be applied in the cases of children who had made no attempt at intra-uterine respiration; but such cases are so rare that this method can scarcely come into any practical use. Blumenstock prophesies that this test will be found as impracticable as the tests of Daniel and Ploucquet, which also depended on the increased blood contents of the lungs in children born alive.—*The Lancet.*

ATHETOSIS IN AN INFANT.—Athetosis of a genuine sort is a clinical rarity in infancy. MM. Comby and Féréol have recently described cases at the Société Médicale des Hôpitaux. Comby's case occurred in a female child aged twenty months, badly fed and rachitic. Various movements were noticed in the toes of the right foot, also in the fingers of the right hand, flexion and extension, abduction and adduction going on incessantly, slowly, without jerkiness, but in exaggerated fashion. The hemiathetosis did not involve the face. General sensibility was intact, and the eyes exhibited no sign of squinting or nystagmus. There was no muscular wasting. The movements began at eight months, were preceded by generalized severe convulsions, which lasted many days. The convulsions left behind them right-sided hemiplegia with athetosis. Cases in which infantile hemiplegia with hemispasm are after several years followed by choreic movements, are by no means rare.—*The Lancet.*

IPECACUANHA SPRAY IN THE TREATMENT OF DISEASES OF THE RESPIRATORY PASSAGES.—From his experience with the use of ipecacuanha spray Dr. William Murrell has published the following remarks: Most successful results are obtained from the employment of the ipecacuanha spray in cases of chronic bronchitis and bronchial catarrh. In fibroid phthisis there is often a marked improvement, even when no constitutional treatment is adopted. A single inhalation will sometimes restore the voice in cases of hoarseness due to congestion of the vocal cords. It is a matter of little importance whether the spray be given with a handball spray apparatus or with a small steam vaporizor. In either case the spray must be warm and the patient should not go out for some minutes after inhaling. Care should be taken to see that the spray really enters the chest and is not stopped by the arching of the tongue against the wall of the mouth. The best results are obtained by using the spray for about ten minutes three or four times a day. In the majority of cases of winter cough relief will be obtained in ten days.—*The Medical Press.*

EVIDENCE OF THE CURABILITY OF PHTHISIS.—Dr. Vibert, who is connected with the Paris Morgue, has stated that among two hundred necropsies which he made on persons who died a violent death, he has in as many as twenty per cent. found evidence of old tubercular lesions in the lungs, which had healed.

COMPLICATED CASE OF OCCLUSION OF THE VAGINA.—An instance of the rare cases in which a woman in labor is found to have complete occlusion of the vagina has been recorded by Dr. Zinsstag, of the Basle Gynecological Clinic. The patient, a young primipara, being in labor, on being examined by her family doctor, was found to have an occluded vagina. He, thinking this arose from stenosis, sent her to the clinic. When first examined there, the finger felt a narrow canal, at the end of which a sharp-edged circular fold separated it from a somewhat more extensive cavity; behind this latter cavity the fœtal head was felt through a thick septum. On inspection, it was discovered that the canal was not the vagina, but a dilated urethra, and the sharp-edged fold the sphincter of the bladder; the cavity was the bladder, and the membrane separating the finger from the fœtal head the posterior vesical wall. From the orifice of the urethra to the fourchette there stretched a strong bluish membrane, across which several veins ran. No opening capable of admitting the finest probe could be found. A somewhat similar case of persistence of the sinus urogenitalis is described by C. Von Braun in his text-book. Coition must have taken place through the urethra, and some opening in the hymen must have existed, permitting the escape of the menses, which had been normal, and also allowing of the introduction of the seminal fluid. This orifice must have become closed up during pregnancy. Incisions were made in the hymen and in the perineum, and the labor was satisfactorily concluded.—*The Lancet.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY
WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, July 28, 1888.

QUININE AND THE TARIFF.

IN 1878, when there was a twenty per cent. *ad valorem* duty on quinine, 196,475 ounces were imported, for which the price was about $2.83 per ounce, and for which consequently we paid about half a million dollars. Last year we imported nearly five million ounces, for which we paid foreign manufacturers only about 73⅓ cents per ounce, or in all about $4,000,000. The decrease in price is due in part, of course, to the increase in supply from the increased culture of cinchona trees.

We are not so sure that cheap quinine is such an unalloyed blessing. It has come about that nearly every family now has its quinine bottle, that it is sold at many general stores, and that the doctor rarely meets an invalid who has not been thoroughly dosed with quinine.

The drug, when taken continuously or excessively, is an injurious one; and its therapeutic value is greatly exaggerated in the popular mind. The value of quinine in "colds," bronchitis, ephemeral fevers, anorexia, general malaise, and various other minor ills, is most problematical.

THE TOXIC DOSE OF OIL OF GAULTHERIA.

SINCE the demonstration that oil of wintergreen is nine-tenths a salicylate and resembles therapeutically the artificially made salicylates, its use in medicine has become quite extended. Although it is a powerful drug, very few cases of serious poisoning by it have been reported, and hence a case recently coming under the observation of Dr. J. G. Pinkham ("Transactions of the Massachusetts Medico-Legal Society," vol. i., No. 10) is of interest.

In Dr. Pinkham's case, the patient, a young woman, took an ounce of the oil for the purpose, probably, of producing abortion. Death occurred in fifteen hours. The symptoms were distress in the head, profuse perspiration, pain in the stomach and bowels, purging, diuresis, with frequent, painful, and, at the last, involuntary micturition, abolition of sight and hearing, general convulsions, tonic spasms of the flexors of hands and feet, great depression of the heart's action, and rapid respiration. *Post-mortem* there was found persistent spasm of hands and feet, great irritation of the gastro-intestinal mucosa, a black, fluid state of the blood, and congested kidneys.

Dr. Pinkham was able to find accounts of only four other cases of poisoning by oil of gaultheria, two of which were fatal. In the three cases which were reported in detail, the amount taken was about half an ounce; and, as in two of these the patients recovered, it may be said, therefore, that the fatal dose of oil of wintergreen is from half an ounce to an ounce.

The symptoms are in many respects like those of salicylic acid. It is possible that the hydro-carbon gaultherilene, which makes up one-tenth of the drug, produces some modifications in the train of toxic phenomena.

It is pretty well established, by the cases so far observed, that at least two drachms of oil of gaultheria could be given without fatal result. As the ordinary dose is ♏x. to ♏xv., every few hours, the drug may be looked upon as a reasonably safe one.

THE LOUISIANA MEDICAL SOCIETY.

THERE are several of our State Societies that are in sad need of some vitalizing influences. Among them, according to the *New Orleans Medical and Surgical Journal*, is the Louisiana State Medical Society.

"A meeting of the Louisiana Medical Society is," says our contemporary, "the straggling together, in some locality, of a dozen or so of languid, inconsequent, unprepared medical men, bent for the most part upon a few days of rest, cigar-smoking, and story-telling."

Other, more specific, criticisms are made. We have at various times perused the somewhat arid records of the Louisiana Medical Society, and are forced to believe that the *Journal* is not far wrong in its strictures. A State with as good a medical school and clinical opportunities as Louisiana possesses, ought to make a creditable showing once a year.

THE HOT-WATER CLYSTER AS A DIURETIC.

DR. M. HOEFLER, of Munich, has made some observations upon the therapeutic value of hot-water enemata which appear to show that they have a special and novel therapeutic value. Dr. Edgar Kurz (*Memorabilien*, xxvii., 9, 1882) has already called attention to the value of such injections in pelvic exudates, and Dr. Dugas (THE MEDICAL RECORD, January 1, 1884) has observed their utility in metrorrhagia and dysmenorrhœa. Their usefulness in constipation and in congested and irritable conditions of the bladder, prostate, and rectum, has long been known.

But Dr. Hoefler's observation is, so far as we can learn, a new one. He finds that hot clysters produce a rapid increase in the urinary secretion. Within three hours the amount is increased three-fold, and after this there is still an increase for the remaining twenty-four hours. One of the recorded experiments is the following:

	Without hot water.	With hot water.
Amount of urine passed from 8 A.M. to 12 M.	213 c.c.	280 c.c.
From 12 M. to 7 P.M.	385 c.c.	1,025 c.c.
From 7 P.M. to 8 A.M.	796 c.c.	995 c.c.

In other words, the daily amount of urine without the clysters was 1,394 c.c.; with the clysters, 2,300 c.c.

The use of medicinal mineral waters containing chlorides and carbonates of sodium had a much less effect.

A series of careful experiments was made in order to determine whether the clysters caused an increase in the amount of urea excreted. The results showed that no especial change occurred, and that the only effect was a lessening of the specific gravity of the urine. On the other hand, it was found that there was an increase in the rapidity of the heart-beat and a lowering of arterial tension, a condition favorable, it is thought, to the removal of congestions and exudation products.

Dr. Hoefler gives the following cautions in the use of the hot-water clysters:

1. The temperature should not be over 45° C. or under 40° C.
2. The injection should be made slowly and carefully.
3. And is best made directly after a movement of the bowels.
4. The patient should lie down for ten minutes or more after the injection, and try to retain it all.
5. The injection-tube should be long enough to be introduced at least ten centimetres.
6. The amount of water should not exceed one litre.

THE MEDICINES THAT CAN BE SAFELY GIVEN NURSING MOTHERS.

A very useful series of experiments has been made by Professor Fehling (*Medical Press*, May 9, 1888; *Therapeutic Gazette*), in order to determine the drugs that may safely be given to nursing mothers. His first conclusion is the very sweeping one, that "all soluble agents, when ingested, may pass into the circulation and be excreted in the milk." An apparent exception to this rule, however, exists in the case of the ferrocyanide of potassium. Among the drugs tested were:

1. Salicylate of sodium, which was found dangerous to the infant in doses (to the nurse) of 45 grains daily.
2. Iodide of potassium, a drug slow in its excretion, and one that may be safely given in doses of 3 grains daily. Such a dose may, however, we are sure, be greatly exceeded in many cases.
3. Iodoform is gotten into the system of the child more easily through the nurse than by giving it directly to the child. Even when the wounds of the mother were dressed with iodoform, the drug was observed in the urine of the child.
4. An important statement, if true, is that mercurial salts given to the mother do no affect the infant at all, or at least very slightly.
5. Experiments with opium and morphine convinced Professor Fehling that 25 drops of tinct. opii (German Pharmacopœia), and gr. $\frac{1}{10}$ to $\frac{3}{10}$ of morphine, could be given safely to the mother.
6. Chloral he found could be given in doses of 23 to 45 grains.
7. Atropine very easily affects the child, even in small doses.

Other points were studied by Professor Fehling, among these the question of the influence of a fever, affecting the mother, upon a child. He found that milk from a fevered mother had no bad influence over the child within certain limits. If the temperature of the mother were very high and long-sustained at 104° F., a corresponding fever curve would soon appear in the child.

He explains this fact by the experiments of Bumm, who found mastitis micrococci in the cellular tissue of the mamma. These microbes were also found in the milk and alimentary canal of the child.

In the septic conditions after confinement, and in erysipelas and scarlatina, the specific micrococci were to be found extensively distributed. In these cases he advises the separation of the child from the mother, and artificial means or a nurse employed to nourish the child. But in the case of any other fevers he thinks the child should be kept to the breast as long as the milk is present, and simple means applied to reduce the fever. Where fever is high and the milk becomes injurious to the child. the milk soon disappears.

In the concluding portion of his paper he discusses the relationship that exists between the nurse and the child, and thinks that it is improbable that a nurse can impart her disposition or character to the child by the medium of the milk alone, though many diseases are likely to be transmitted, he admits, by this means. He thinks, however, that mothers with any tendency to mental disorders or epilepsy should not suckle their own offspring. It is condemned as a false notion, however, to suppose that the temperament or corrupt disposition of a nurse can be transmitted to the child in the same manner that disease can be communicated.

It is hard to conceive how a mother's milk can carry with it any specific epileptic or psychopathic taint, though it might easily be poor stuff to nourish a child, just as is the milk of any sick animal. Still experience must decide whether it is wise to let an epileptic or neurotic mother nurse her child, and experience is rather against the practice.

With regard to the general diet of the mother, Dr. Fehling thinks that the practitioner should correct the public notion of prohibiting certain food-stuffs, such as acids or salads. He conducted his experiments with citric acid, mineral acids, and vinegar. As might be expected, no proof of their transmission to the child could be proved, and no disturbance in the general condition of the child was observed. The child during the experiments rested as well before as after the experiments were performed; its functions of secretion and excretion were normal; while the mother's milk remained alkaline during all the experiments.

PROPRIETARY MEDICINES AND ADVERTISING DRUGGISTS.

A drug firm in this city, which has been well supported by the medical profession, is sending out advertisements of "——'s Remedy for Gout, Neuralgia, etc." No description of its constituents is given in the circular, which is worded so that the public can independently buy and use the remedy. We can see very little difference between thus foisting some secret "remedy" on the public, and deliberately assuming the agency for a patent medicine. Remedies for gout, neuralgia, and rheumatism, if efficient. can never be very safe in the hands of laymen. The practice of advertising a drug as a "remedy," not as a drug, is in accordance with the methods of the quack; and firms which strive to put "six-fold" remedies on the public can hardly deserve the confidence of the profession. The circular we refer to states that ninety-nine per cent. of cases of organic disease of the heart are due to the use of liniments and external applications! The sending of circulars and agents with such statements to educated physicians, is a piece of the rankest impertinence.

We trust that our readers will remember this quack remedy for gout, and the methods of its proprietors.

News of the Week.

It is not often that literary degrees are conferred on account of distinguished surgical services, but at the Commencement exercises of Union College, June, 1888, the honorary degree of LL.D. was conferred upon Mr. Lawson Tait, of Birmingham, England.

Dr. George H. Mitchell died at Los Angeles, Cal., on June 17th, in the fifty-first year of his age. Dr. Mitchell at one time practised medicine in this city, and was connected with the Board of Health. He was an army surgeon during the war.

Dr. Hermann Knapp has been appointed Professor of Ophthalmology in the New York College of Physicians and Surgeons, as successor to the late Dr. C. R. Agnew.

The Brinkerhoff Treatment.—A correspondent asks for the especial points of merit in the Brinkerhoff treatment, and we shall be glad to publish any experiences in this line.

The Oldest living Graduate of the University of Pennsylvania is not, as we stated, Dr. Hiram Corson, but Dr. John T. Huddleson, of Delaware County, Pa., who graduated in 1824.

Mr. Daniel A. Jones has contributed $100,000 for the erection of a wing to the Presbyterian Hospital of Chicago.

A Clinical School at Detroit.—The matter of establishing a clinical school in Detroit, as a department of the University of Michigan, has finally taken definite form. The new movement is to raise $200,000, to be placed in the hands of the regents, to be used for the establishment of such a clinical department. About sixty thousand dollars has already been raised.

Mackenzie and the German Physicians.—An esteemed correspondent, of Lincolnville, Kan., takes exception to the criticisms made by us upon the report of the German surgeons concerning the case of the late Emperor. He says: "If the German physicians were right and Dr. Mackenzie wrong, why should not the world, at least the medical portion of it, know it? The subjects of the lamented dead Emperor have a right to know the truth. Are not the professional reputations of the eminent German physicians entitled to this statement of vindication? Aside from a question of absolute justice and beneficial results of the report, where is the human being who, in the situation of those physicians who diagnosticated cancer, would not desire, nay claim, a right to have the correctness of his diagnosis made known to the world? Thousands outside the medical ranks wish to know who was right. Is there any *wrong* in that they should know the *right!*" Our correspondent mistakes the ground which we took in criticizing the report. We quite agree with him in wanting to have the truth known. But the report was a partisan and personal one, inspired by political influences, and not signed by Virchow, Leyden, Bardeleben, Senator, or Krause of the attending physicians and surgeons. It was given to the public press, not to the profession, and was intended to serve personal rather than scientific ends. Such is the view which, without any bias, we have felt compelled to take of the matter. This view is further supported by demonstrable inaccuracies in statements made in the report, such as that Dr. Mackenzie injured the right vocal cord, and that the impairment of the motion in the left vocal cord was not observed early in the disease.

The Jay Gould Medical College has been recently organized in Memphis, Tenn.—*South-Western Medical Gazette.*

The Indiana State Medical Society carries off the honors this year among successful annual meetings. We are not quite so certain about its scientific work, but the social features, and especially the banquet given by the Marion County Society, showed that our Hoosier friends possess wit, poetry, and oratorical powers of a superior order. There were two good poems, many bright speeches, a kind of spook-letter from the long-dead Daniel Drake, and a telegram from Bill Nye, as follows:

"Sorry I cannot be there. May you and associates continue to take life easily, as heretofore.

"Bill Nye."

This was received with great applause, which commenced as a murmur and increased to a roar.

Electric Light produces, as is well known, disturbances of vision among the workmen who are exposed to it. We refer, of course, to the large arc lights. The injuries that result have been described in The Medical Record. Recently a new pathological result of working in intense light has been reported to the Paris Surgical Society. The cases were those of workmen at Creusot, where an electric furnace is used for quickly melting metals. The men suffer greatly from the effects of the intense light, which exceeds a hundred thousand candle-power. After one or two hours the workers have a painful sensation in the throat, face, and temples, while the skin becomes copper-red in hue, and an eye-irritation lasts forty-eight hours, the discharge of tears being copious. After five days the skin peels off. All these effects are produced by light alone, no heat being felt. Dark-colored glass mitigates the effects somewhat, but does not entirely prevent them.

The Binghamton Asylum in this State has had a curious history. Originally it was started as an Inebriate Asylum (in 1854). It was built by a stock company as a private undertaking, and received its charter from the State. Drs. John W. Francis, Valentine Mott, and Willard Parker were among the presidents of the Managing Board. In 1867 there was a reorganization of the Board, and the institution was deeded to New York State for the sum of one dollar. This was done, according to the *Journal of Inebriety*, by the managers without the advice or consent of the stockholders. In 1879 the State turned the Inebriate Asylum into an Insane Asylum. The *Quarterly Journal of Inebriety* says that the action of the Board was illegal, and that the question of title is now to be decided in the courts.

This is a Warm Season for both the soma and the psyche; the summer solstice disturbs the one, the presidential campaign the other. It behooves, therefore, the man of philosophic mind, and such the true physician must ever be, to keep as cool as possible. He will remember that, tariff-reform or not, the death-rate continues at 18 per 1,000, and (*pro bono medico*) the sick-rate 400 per 1,000 annually. We disinterestedly advise all Republicans to vote for Mr. Harrison, all Democrats to vote for Mr. Cleveland, and both parties to read The Medical Record, which will continue to present the latest and most practical observations made as the Torch of Science advances.

The Transplantation of the Rabbit's Cornea.—*A propos* of the recently hastily reported case of this kind at Baltimore, Dr. F. E. Holtz writes to the *Journal of the American Medical Association*: "If those who imitate Prof. von Hippel's operation would only imitate also his patience and conscientiousness, and wait for the final results of their operations, their reports would be of more scientific value. For ten years Professor von Hippel had been trying to find a method of preserving the transparency of the transplanted cornea, and at last he succeeded in two cases which he reported last year at the meeting of the German Ophthalmological Society. But to feel warranted in reporting the result as a lasting success, he had been watching the one case twenty-one months and the other case three months after the operation. He did not operate one week before the expected meeting and then hurry there to have the success of this 'wonderful' operation heralded all over the country.

"There is another thing that the reporter of Dr. Chisolm's case might learn from the German professor, to wit, modesty and moderation in stating the possibilities of the operation. Hippel himself pronounced the usefulness of his operation in its present form to be very limited, because it was applicable to those cases only in which the opacity (leucoma) covered the cornea so far that an iridectomy could not improve the sight, but where at the same time the opacity did not extend through the *entire* thickness of the cornea. But, he said, these conditions are very rarely found: and by far the larger majority of cases in which we would like to employ corneal grafting, are *total leucomata*, where the *whole* thickness of the cornea has been transformed into opaque, cicatricial tissue; and besides, in most of these cases the iris is adherent to the posterior surface of the leucoma."

The Tariff on Microscopical Apparatus and Scien-

[illegible] pharyngeal catarrh in young girls fifteen to twenty years of age, who are decidedly anæmic and chlorotic and who suffer with constipation, and I have found that this was the cause of the catarrhal symptoms.

Dr. S. D. Risley, of Philadelphia: It is pretty generally admitted that nasal and pharyngeal diseases are especially liable to occur in persons of a gouty diathesis. Naso-pharyngeal disease is one of the most uniform manifestations of lithæmia. From the symptoms detailed in regard to the first case of Dr. Buck, I should suggest that the digestive disturbance was probably associated with a lithæmic condition.

Dr. C. H. Burnett, of Philadelphia: The use of nitrate of silver has been referred to. While this may be of service in other locations, I think that it is the worst application that can be made to the nose or the naso-pharynx.

Dr. S. Sexton, of New York: I have seen many cases in which irritation in the mouth has been the cause of naso-pharyngeal catarrh and aural symptoms.

Dr. J. F. Noyes, of Detroit: I have always recognized these so-called reflex causes, and have treated cases by searching out these causes. A remarkable case came under my notice of a lady who, after confinement, developed naso-pharyngeal catarrh. There was profuse secretion. The trouble continued for a year, in spite of treatment. Finally she passed into the hands of a gynecologist, and the cause was then discovered, and treatment of the uterine disease cured the naso-pharyngeal disease.

Dr. Samuel Theobald, of Baltimore: I think that where atrophy follows hypertrophic catarrh it is the result, not of the application of nitrate of silver but of the continuance of the catarrh.

Dr. Charles J. Kipp, of Newark: I agree with Dr. Theobald as to the value of nitrate of silver. I rarely use it in a stronger solution than twenty grains to the ounce, and neutralize it afterward by salt water.

Dr. A. H. Buck, of New York, then read

A CONTRIBUTION TO THE ANATOMY OF THE ELEPHANT'S EAR.

The ear was exhibited, and the interesting points indicated. The external auditory canal is embedded in air-containing cells, and is six and a half inches long. The canal at the time of examination was filled with desquamated material. In the middle ear, the handle of the hammer seems to lie in a horizontal plane; it is not vertical, as in the human being. The anterior part of the drum-cavity is completely cut off from the posterior part. The Eustachian tube comes up through a system

Dr. George Hay states, in the *Pittsburg Medical Review*, that having been poisoned several times by canned lobster and canned salmon, he investigated the character of the tin cans and found them to consist of about one-fifth tin, four-fifths lead, with a little iron.

Menthol and Saffrol, the so-called camphors of peppermint and sassafras oil, respectively, are said by Dr. C. L. Dana (*Therapeutic Gazette*) to possess decided anodyne properties, given internally. Menthol (gr. v. to x. in hot water) relieves migraine and neuralgic pains. Saffrol, ℳ xx. to xxx., is also effective in acute and subacute rheumatism.

A Summer Drink for Children, proposed by Dr. Duchesne, of Paris, is the following: Glycyrrhizin, gr. xvi.; powdered sugar, gr. xvi.; bicarbonate of sodium, gr. xii.; crystallized quassine, gr. $\frac{1}{200}$; oil of anise, gt. $\frac{2}{3}$. M. For one powder. This quantity is to be dissolved in one quart of water when wanted for use. The beverage costs about half a cent a quart.

A Correspondent desires to know if the claims for "lithiated hydrangea" have any grounds in the actual experience of physicians. We can only say that it has been spoken of with a fair degree of commendation.

Another Heart Tonic has apparently been found in neriatin, the active principle of nerium odorum, or oleander. Under the control of Dujardin-Beaumetz, Dr. Pouloux has, says the *Therapeutic Gazette*, made a few studies of the influence of oleander in cases of heart-disease. He affirms that under its action the beat of the failing heart has become regular, and the filiform, imperceptible pulse full and hard. In several of the cases there has been marked increase of the urinary secretion, and in some the disappearance of wide-spread œdema. He administered the extract in pill form in doses of five centigrammes.

to the use of liniments and external applications! The sending of circulars and agents with such statements to educated physicians, is a piece of the rankest impertinence.

We trust that our readers will remember this quack remedy for gout, and the methods of its proprietors.

News of the Week.

IT IS NOT OFTEN THAT literary degrees are conferred on account of distinguished surgical services, but at the Commencement exercises of Union College, June, 1888, the honorary degree of LL.D. was conferred upon Mr. Lawson Tait, of Birmingham, England.

DR. GEORGE H. MITCHELL died at Los Angeles, Cal., on June 17th, in the fifty-first year of his age. Dr. Mitchell at one time practised medicine in this city, and was connected with the Board of Health. He was an army surgeon during the war.

DR. HERMANN KNAPP has been appointed Professor of Ophthalmology in the New York College of Physicians and Surgeons, as successor to the late Dr. C. R. Agnew.

THE BRINKERHOFF TREATMENT.—A correspondent asks for the especial points of merit in the Brinkerhoff treatment, and we shall be glad to publish any experiences in

The next paper was by DR. C. H. BURNETT, of Philadelphia, entitled

A CASE OF AURAL VERTIGO (MENIÈRE'S DISEASE) RELIEVED BY EXCISION OF THE MEMBRANA TYMPANI AND MALLEUS.

The patient was a young unmarried woman, thirty-seven years of age, who six years previous had been under treatment for chronic naso-pharyngeal catarrh, and chronic catarrh of the left middle ear, accompanied with hardness of hearing, tinnitus aurium, and a sense of fulness in the affected organ. Treatment of the catarrhal disease of the ear produced no benefit. After the lapse of six years, the symptoms already named grew worse, and there was superadded marked aural vertigo. The membrana tympani in the line of the malleus handle was found adherent to the promontory, and the consequent retraction of the entire chain of bones was held to be the cause of the aural vertigo and the sense of fulness, and of the tinnitus.

The operation of excision of the membrana tympani and the malleus was performed under ether, May 21st last, with entire and immediate relief to the aural vertigo (which before had often been sufficient to cause the patient to hold to a lamp-post for support) and to the sense of pressure and tinnitus, which good result has been maintained to the present time. The hearing was practically unaffected by the operation. The incus was detached from the stapes but could not be removed, as it slipped into the attic, and grappling for it is not advisable on account of the risk of irritation. Its removal, furthermore, would have no effect on the result of the operation.

DISCUSSION.

DR. J. O. TANSLEY, of New York: I have now under my observation a girl on whom the operation was performed some eighteen months ago. When she came to me the whole internal canal was filled with polypi, and she presented serious brain symptoms. I took out all the polypi and found a portion of the drum remaining, and above a localized necrosis into which a probe passed at least one-fourth of an inch. The patient has been under observation every day for two months. The local necrosis is healed, and she is doing well. There are still some brain symptoms. It seems to me that this is a very serious operation, and I should hesitate some time before performing it, on account of the results that might occur. In this case the result seems directly traceable to the operation.

DR. C. H. BURNETT, of Philadelphia: My patient did not remain in Philadelphia, but I was informed that two or three weeks after I saw her a discharge appeared. I think that there is still a slight discharge, but the membrane is forming. In another case a slight discharge appeared soon after the operation, but ceased after the membrane had reformed. The case reported by the last speaker was not one of the class to which I have alluded. The operation was evidently not properly performed if there remained a portion of the membrane and there was necrosis. I have not found this a dangerous operation. No one has reported bad results from this operation properly performed.

DR. CHARLES J. KIPP, of Newark: This operation has been performed a number of times by a foreign operator for the relief of tinnitus and vertigo, but he has given it up because it did not relieve these symptoms satisfactorily. He, however, did not have any bad results.

DR. S. SEXTON, of New York: I have performed this operation between fifty and one hundred times in the past few years, and have obtained decided benefit in a number of cases of tinnitus and other subjective symptoms. I have known of no case in which there was aggravation. In many cases, where there has been no marked tinnitus, the distressing sense of pressure has been overcome. The tinnitus is not always relieved by the operation.

Dr. Burnett has referred to the closure of the drum-head. My principal endeavor has been to avoid reformation of the drum-membrane. In a number of cases where this occurs the good hearing is lost. I have prevented this by the application of a solution of salicylic acid in ether to the margin of the closing membrane. This has succeeded even where the membrane has closed down to a minute opening. In regard to the purulent cases to which allusion has been made, I have operated on a number, and, on the whole, they are the more satisfactory cases.

Dr. S. Sexton then exhibited a new

PORTABLE BATTERY FOR THE STORAGE OF ELECTRO-MOTOR FORCE,

and a new

HEAD-LANTERN FOR THE EMPLOYMENT OF ELECTRIC LIGHT IN SURGERY.

The battery was made at his suggestion by the River & Rail Electric Light Co., of New York. It consists of three cells, and will light a six-candle electric light. The lantern is a modification of that of Trouve, but much lighter, and having a non-conducting base. Such a light is almost necessary in operations on the ear, when ether is used as an anæsthetic. The battery will work continuously for twenty-four hours, and will retain its power for several weeks or months. It may be charged by a dyna-

ous history. Originally it was started as an Inebriate Asylum (in 1854). It was built by a stock company as a private undertaking, and received its charter from the State. Drs. John W. Francis, Valentine Mott, and Willard Parker were among the presidents of the Managing Board. In 1867 there was a reorganization of the Board, and the institution was deeded to New York State for the sum of one dollar. This was done, according to the *Journal of Inebriety*, by the managers without the advice or consent of the stockholders. In 1879 the State turned the Inebriate Asylum into an Insane Asylum. The *Quarterly Journal of Inebriety* says that the action of the Board was illegal, and that the question of title is now to be decided in the courts.

ance played the part of a promoter of naso-pharyngeal catarrh or of aural disturbance. Some of those indirect causes which he had observed were then enumerated. Irritation of the gastro-intestinal canal is, in not a few instances, a strong exciting cause of naso-pharyngeal catarrh, and of all the aural disturbances growing out of such a catarrh. A male, forty-five years of age, had for years been more or less a sufferer from naso-pharyngeal catarrh, with tinnitus aurium and slight impairment of hearing, and more recently had begun to suffer from feeble digestion. He noticed that after indulgence in certain articles there would be abdominal discomfort, and at the same time marked exacerbation of the naso-pharyngeal catarrh. So long as the offending substance was in the stomach there was only a slight sense of discomfort, but in the course of three or four hours a slightly painful peristaltic movement would set up in the bowels; simultaneously the secretion from the vault of the pharynx would become unpleasantly active, and the tinnitus would increase. This condition would last for an hour, and then the naso-pharyngeal catarrh would return to its usual state. These attacks were accompanied with the escape of large quantities of gas by eructation. In many patients, usually men between forty and sixty years of age, where we have reason to believe that the gastro-intestinal tract is habitually in a state of greater or less irritation, we find the faucial mucous membrane red and swollen; in these cases the disease which claims chief attention is the gastro-intestinal affection.

Reflex influence, involving the vault of the pharynx and the ear, may emanate from more distant sources. A lady, forty years of age, complained of distressing tinnitus, involving both ears. There had been mild naso-pharyngeal catarrh, from time to time, for many years. At times she was almost entirely free from tinnitus. I always succeeded in giving prompt relief by applying a moderately strong solution of silver nitrate with a mop of absorbent cotton to the vault of the pharynx. After a time these failed to give relief. It was then learned that for many years she had suffered with pain in the pelvic regions and back, and that at this particular time she was suffering in a more marked degree. A specialist was then consulted, and it was found that there was retroversion of the uterus and subacute parametritis. These conditions were removed, and the tinnitus disappeared without treatment to the vault of the pharynx.

The author states that he had spoken of these as indirect causes; that is, as factors competent to aggravate a pre-existing but perhaps latent catarrhal disease, but he saw no reason why these reflex influences may not in certain cases play the part of direct exciting causes. He considered it impossible to demonstrate the correctness of this belief, and therefore preferred to adopt the view which assigns to them a less independent rôle.

DISCUSSION.

Dr. J. O. Tansley, of New York: I meet with many cases of naso-pharyngeal catarrh in young girls fifteen to twenty years of age, who are decidedly anæmic and chlorotic and who suffer with constipation, and I have found that this was the cause of the catarrhal symptoms.

Dr. S. D. Risley, of Philadelphia: It is pretty generally admitted that nasal and pharyngeal diseases are especially liable to occur in persons of a gouty diathesis. Naso-pharyngeal disease is one of the most uniform manifestations of lithæmia. From the symptoms detailed in regard to the first case of Dr. Buck, I should suggest that the digestive disturbance was probably associated with a lithæmic condition.

Dr. C. H. Burnett, of Philadelphia: The use of nitrate of silver has been referred to. While this may be of service in other locations, I think that it is the worst application that can be made to the nose or the naso-pharynx.

Dr. S. Sexton, of New York: I have seen many cases in which irritation in the mouth has been the cause of naso-pharyngeal catarrh and aural symptoms.

Dr. J. F. Noyes, of Detroit: I have always recognized these so-called reflex causes, and have treated cases by searching out these causes. A remarkable case came under my notice of a lady who, after confinement, developed naso-pharyngeal catarrh. There was profuse secretion. The trouble continued for a year, in spite of treatment. Finally she passed into the hands of a gynecologist, and the cause was then discovered, and treatment of the uterine disease cured the naso-pharyngeal disease.

Dr. Samuel Theobald, of Baltimore: I think that where atrophy follows hypertrophic catarrh it is the result, not of the application of nitrate of silver but of the continuance of the catarrh.

Dr. Charles J. Kipp, of Newark: I agree with Dr. Theobald as to the value of nitrate of silver. I rarely use it in a stronger solution than twenty grains to the ounce, and neutralize it afterward by salt water.

Dr. A. H. Buck, of New York, then read

A CONTRIBUTION TO THE ANATOMY OF THE ELEPHANT'S EAR.

The ear was exhibited, and the interesting points indicated. The external auditory canal is embedded in air-containing cells, and is six and a half inches long. The canal at the time of examination was filled with desquamated material. In the middle ear, the handle of the hammer seems to lie in a horizontal plane; it is not vertical, as in the human being. The anterior part of the drum-cavity is completely cut off from the posterior part. The Eustachian tube comes up through a system of air-cells and opens through one of them close to the drum-membrane. Under the floor of the tympanic cavity there are three septa, making stall-like spaces. Two of these are quite long, six or seven inches. The labyrinth and other parts were not examined.

A paper by **Dr. Huntington Richards**, of New York, was then read by Dr. Buck, on

A CASE OF POLYPOID ANGIOMA OF THE EAR.

The patient, a girl, six years of age, came under observation May 4, 1888, with profuse and badly smelling otorrhœa, unaccompanied by pain, and dating only from the preceding February. Hearing seemed good. No bleeding from the ear had ever been observed. The general health was excellent.

Examination of the affected ear revealed a polypoid mass almost occluding the canal; the color was deep purplish-red. A considerable portion of the tumor was at once removed with the snare, and the remainder of the growth was extracted on the following day, leaving a small pedicle attached, seemingly to the outer surface of the drum-membrane, close to the prominence formed by the short process of the hammer. This stump was cauterized with chromic acid. Hemorrhage from the cut surface of the growth was unusually profuse at both operations. The child's hearing is now excellent, although both membranes are depressed and of a dark grayish-red color. The removed growth was pronounced to be an angioma. Three micro-photographs showing the appearance of the growth were exhibited.

Dr. Huntington Richards, of New York, also sent a paper, read by Dr. Buck, on

A CASE OF "FALSE DRUM MEMBRANE."

The patient, a man, twenty-one years of age, was totally deaf in the affected ear. There was a vague history of an attack of otitis media in early childhood. The other ear presented the common appearance of otitis media purulenta chronica. Examination of the ear that was not discharging showed a membrane occluding the canal. It differed from the normal drum-membrane in color, shape, relation of its plane to the long axis of the canal, and apparent thickness. It varied little in color from the skin lining the canal. The surface was perfectly smooth.

A triangular opening was made through this membrane. This caused no pain. Through this opening it was seen that there was no drum-membrane, but the inner wall of the tympanic cavity came into view. The hearing was only slightly improved. When seen a few days later, no discharge had appeared. Since that time he has not returned to the infirmary.

DISCUSSION.

Dr. S. Sexton, of New York: In a case seen last year I removed the membrane and then took out the malleus and incus. This case made a good recovery. The improvement in hearing was decided.

Dr. T. Y. Sutphen, of Newark: I have seen one or two cases of this trouble, which seems to me to be due to cicatricial closure of the external canal. It seems to me that the condition would be best spoken of as cicatricial closure of the canal.

Dr. A. Mathewson, of Brooklyn: A lady was under my care for some time, with an eczematous condition of the external meatus. She then passed from observation. Some time later she presented herself with a disk-like closure of the external canal. This was not complete, as there was a small opening in the centre. I dilated this opening with laminaria bougies, and the ear was left in perfect condition.

Dr. Samuel Theobald, of Baltimore: The members may recall a case which I reported, in which there was occlusion of both external canals. There was a history of suppuration, and, no doubt, there was ulceration and gradual closure.

Adjourned until evening.

Evening Session.

Dr. J. B. Emerson, of New York, read a paper on

THE FLEXIBLE CATHETER AS A DRAINAGE-TUBE—WITH CASES.

The author cited several cases, exhibiting the use of the flexible catheter as a drainage-tube.

With deeply seated inflammation of the auditory canal or mastoid cells, maintenance of drainage through a fistula is a necessity; and to prevent closure of the fistula, either by granular growth or natural healing, is important.

Dr. Emerson recommends the use of the flexible catheter as generally the best means to employ, and states his reasons to be, the comparative comfort and safety, together with convenience of control by both surgeon and patient. The efficiency observed in the use of the flexible catheter was also referred to.

Dr. Charles J. Kipp, of Newark, reported on

THREE CASES OF TRANSIENT BILATERAL HORIZONTAL NYSTAGMUS IN CONNECTION WITH PURULENT INFLAMMATION OF THE MIDDLE EAR.

Case I.—A young man, twenty-one years of age, had had otorrhœa seven or eight years previously. Three months before coming under observation he had an acute exacerbation, and suffered intensely with pain in the ear and head. The otorrhœa much diminished. Two or three weeks later he came, stating that he saw objects double, was dizzy, and could not walk. There was marked nystagmus in a horizontal direction. The vertigo and nystagmus continued four days. With the cessation of the nystagmus the vertigo disappeared.

Case II.—A young man, treated six years previously for acute otitis media purulenta, ending in recovery, appeared in March with an acute attack. Paracentesis was performed. The pain, however, continued for a long time. Finally, swelling developed behind the mastoid, and this was accompanied with several epileptiform attacks. One day, pressing on the swelling, pus poured from the canal. With this there was a sudden jerk of the head and nystagmus. The latter continued for about ten minutes. This was produced every time pressure was made on the mastoid. The mastoid was subsequently opened; since then there has been improvement.

Case III.—A young man, after exposure, was seized with intense pain in the ear, followed by otorrhœa. When he came under observation there was great pain. This was not relieved by treatment, but continued two or three weeks. Then a swelling appeared below the ear. This was incised and a large quantity of pus evacuated, with relief to the pain. Some days later, while washing out the cavity, the fluid came through the ear when considerable force was used. At the same time there was a jerk of the head and nystagmus, continuing several minutes. This could always be produced by making forcible injection.

Dr. J. O. Tansley, of New York, exhibited

AN IMPROVED AURAL SNARE.

The snare was devised to overcome an objection to the ordinary Wild snare; that is, the little jerk and rebound of the instrument when the growth is cut through. The instrument exhibited consists of a small tube through which the wire passes, to be connected with a small bobbin, by the turning of which it is gradually shortened.

A paper by **Dr. S. Sexton**, of New York, on

FOREIGN BODIES IN THE EXTERNAL AUDITORY CANAL,

was read by title.

Executive Session.

The following officers were elected:

President—Dr. J. S. Prout, of Brooklyn.

Vice-President—Dr. Gorham Bacon, of New York.

Secretary and Treasurer—Dr. J. J. B. Vermyne, of New Bedford, Mass.

Committee on Membership—Dr. A. Mathewson, Dr. D. B. St. John Roosa, and Dr. John Green.

Delegate to Congress of American Physicians and Surgeons—Dr. W. H. Carmalt, of New Haven; *Alternate*, Dr. G. Bacon, of New York.

The Society then adjourned, to meet at the Arlington Hotel, Washington, D. C., Tuesday, September 18, 1888.

Adjourned.

Knowsby Thornton on the Treatment of Uterine Fibroids by Electrolysis.—Dr. Thornton writes as follows to *The British Medical Journal:* 1. I think the whole discussion premature, because we know that fibromyomata are most uncertain in their habits of growth and retrogression when left entirely to themselves, the most surprising alterations taking place in periods of three, six, or twelve months. Such alterations are still more common if the patients are carefully handled as to diet, alcohol, rest at the periods, and special medicine. 2. Nothing which has yet been published by Apostoli or his followers is inconsistent with these natural, or slightly aided, changes, and the results obtained are probably as much due to the rest and care while under treatment, powerfully aided by the effect on the nervous system of confident hope of cure, as to the specific action of electricity. 3. No results can have any scientific value till the cure is proved by a sufficient interval of health for at least twelve months after the treatment has ceased. 3. We do not yet fully appreciate the dangers of the method. I know of one case in which rapidly fatal pyæmia followed a very few applications in the hands of one experienced in the use of the method. The journals tell us of narrow escapes, and even such careful manipulators as the Keiths record a serious case of cellulitis, of which the gravity is not lessened by attributing it to the carelessness of the patient. 5. I would ask the profession not to be carried away by the enthusiasm of anyone in a *revival* of this kind, but to wait patiently for definite results, confirmed by sufficiently long intervals.

KENTUCKY STATE MEDICAL SOCIETY.

Thirty-third Annual Session, held at Crab Orchard Springs, Ky., July 11, 12, *and* 13, 1888.

DR. JOHN G. BROOKS, OF PADUCAH, PRESIDENT, IN THE CHAIR.

DR. STEELE BAILEY, OF STANFORD, SECRETARY.

(Special Report for THE MEDICAL RECORD.)

DR. E. W. PALMER, of Louisville, Chairman of the Committee of Arrangements, in opening, made a few remarks.

NEW MEMBERS.

The following gentlemen were received as new members: W. L. Rodner, E. B. Schrieber, H. M. Busey, F. W. Kehler, all of Louisville; A. G. Lovel, Mount Vernon; T. B. Green, Bloomfield; J. W. Gilbert, of Lawrenceburg; W. H. Roach, of Mercer County. The Society has lost by death during the past year Dr. W. G. Ouchterlony, of Louisville.

DR. J. W. IRWIN, of Louisville, made a report on

PROGRESS IN OBSTETRICS,

in which he considered the subjects, Cæsarian Section, Electricity in Obstetrics, and Operations on the Perineum.

DR. J. MORRISON RAY, of Louisville, read a report on

THE PROGRESS IN OPHTHALMOLOGY.

Novelties in this branch he found not now so numerous as a short time since. The modern cataract operation, he thought, required some attention. The after treatment of cataract was undergoing some revolution. It was not thought to be so important as formerly. The late Dr. Agnew was the first to teach that light should not be excluded from cataract operations. Many others are following his teaching with good results. Much success in ophthalmic operations is now due to the use of antiseptics. Solution of the bichloride of mercury, 1:5000, or a dilute solution of argenti nitratis, are probably the best. The use of hydrochlorate of erythrophlœine as a local anæsthetic is objectionable, as Theobald, of Baltimore, has shown it brings on an attack of glaucoma in many cases. It is doubtful if it has any advantage over cocaine except that its effect is of longer duration. Antipyrine has come into use to control pain in the eye. Modern ophthalmology is striving to show a closer connection between eye diseases and general practice.

DR. DUDLEY S. REYNOLDS, of Louisville, said that he could not agree with the gentleman that suppuration depended on the depth of the incision in the cornea. In antisepsis it is very material to get an

EXACT MEASUREMENT,

and this we do not do when we compare grains and drops. We should go measure for measure, or weight for weight. He thought a better way was the way in which he used it, viz., one grain to the pint of distilled water. Marsden it was who determined the fact that the little rice-grained bodies found determined the disease. In granular lids trachoma is one of the manifestations of malarial disease, as has been found in India. He regretted that the pilocarpine treatment of glaucoma had been alluded to. The relation of defects of refraction to muscular defects of the eye and their combined effects on the general system, are interesting questions. The connection between the genito-urinary system and the eye is well known. He reported the case of a boy who was troubled with a spasmodic twitching of the eye, which disappeared on the removal of a lengthened prepuce.

DR. S. G. DABNEY, of Louisville, had seen the bichloride solution, 1:2000, irritate the conjunctiva very much, causing an ophthalmia. His experience with erythrophlœine had been to the extent of but one case. He wished to protest against the use of iodoform as an antiseptic in eye diseases. He had seen it used in Prague very extensively, and he thought it the most disagreeable antiseptic which could be chosen.

DR. M. F. COOMBS, of Louisville, thought that the extent of the cut influenced suppuration.

DR. J. H. BUCKNER, of Cincinnati, agreed with Dr. Reynolds that the danger from suppuration was from infection not from incision. Antiseptics, he thought, had done much for eye surgery. He was surprised to find so much apprehension from the use of strong solutions of the bichloride. He had been in the habit of using one grain of the bichloride to two ounces of the combined mixture of water, wine of opium, and glycerine, about 1:1000.

He agreed with Reynolds as to the confusion arising from the indiscriminate use of the terms ounces and grains. He did not believe eserine a safe remedy to rely on indefinitely in the treatment of glaucoma.

THE YOUNG OCULIST

is too apt to see only a sore eye and to forget that many eye cases are due only to constitutional conditions and to get well need only to see his brother, the general practitioner.

DR. RAY, in concluding the discussion, said he thought Dr. Reynolds had misunderstood him. He thought suppuration could be prevented in many cases by the use of antiseptics. He thought that too much stress had been laid on the difference between hypertrophy of the conjunctiva and trachoma. He wished to emphasize the importance of iridectomy in acute glaucoma. He thought we could make the cataract operation and send the patient home from the office and have about as good results.

DR. I. N. BLOOM, of Louisville, made a report on

PROGRESS IN DERMATOLOGY.

Science in this department has made steady progress during the past year, yet, nothing startling has been developed. Anthrarobin and chrysarobin have attracted considerable attention. The treatment of syphilis with insoluble mercurials hypodermically is attracting considerable attention and is followed by good results. The contest for supremacy lies between calomel and yellow oxide. America has been strangely conservative on this subject, while grand results come to us from Germany, France, and Italy. He had used the yellow oxide in fifteen cases and only one had an abscess. He urged the profession to make a trial of this method—the injection of insoluble mercurials for syphilis. He quoted a preponderance of authorities going to show the identity of lupus and tuberculosis.

DR. J. CLARK MCGUIRE, of Louisville, was of the opinion that lupus and tuberculosis were not identical. He quoted authorities to the proportion of seventeen out of twenty-seven, to substantiate his belief. In eczema he recommended the fixed adhesive dressing recommended by Professor Unna. He was opposed, on a theoretic ground, to the hypodermic injection of the insolubles in syphilis, and was backed by the authorities. If six or eight injections

'CURE" SYPHILIS,

then there must be a remaining reservoir of the poison hidden in the system. He thought the method by inunction the superior one. The bacilli of lepra, and of tuberculosis are considered the same in appearance.

DR. DUDLEY S. REYNOLDS, of Louisville, said the baccilli of lepra and tuberculosis were not the same in scarcely any particular.

DR. MCGUIRE replied that he did not make the statement of the identity of the two bacilli on his own authority, for he knew nothing about it, but upon the authority of Chiari, who was equal, at least, to anybody in Kentucky.

Dr. Archibald Dixon, of Henderson, had used the

HYPODERMIC INJECTION OF CALOMEL

in one case, where a man wanted to marry and be rid of his syphilis in a hurry. The injection was followed by a serious abscess, but all appearance of syphilis disappeared. He had not used the treatment since. He did not like to see anything condemned without trial in a fair way. Abscesses in calomel injections are now reduced to two per cent., and those in yellow oxide to nothing. My abscess was due, I think, to my omitting to disinfect the needle and part injected. Five and six hundred cases are reported where no abscess followed the use of yellow oxide.

Dr. J. G. Carpenter read a paper on the

DILATATION OF STRICTURE ANI.

The etiology, he thought, was often constipation in childhood. It comes on also reflexively, and was often due to retroflexion of the uterus.

This being literally the tail end of the discussion of the day, supper being ready, and the band playing, an adjournment was made.

Dr. W. O. Roberts, of Louisville, reported a case of

NEPHRECTOMY FOR SARCOMA.

The patient was a German girl, aged five years and six months, whose family history had been good. She complained for a considerable period of pain in the abdomen. She then had scarlet fever and then a tumor was detected in the left side of the abdomen just beneath the ribs and about the size of a fist. It was thought to be an enlarged spleen and treated accordingly. The tumor increased in size, downward, forward, and inward. The child complained of pain, referring it to the belly and to the back. She became greatly emaciated, and the outlines of the tumor could be readily made out. Its anterior surface was somewhat nodulated. Nothing abnormal appeared in the urinary secretions. A number of medical gentlemen saw the case, and all agreed that the only relief was in the removal of the tumor. An incision was made in the median line six inches long, with the umbilicus as the centre. The tumor was found situated behind the peritoneum and resting on its anterior surface was the colon, which was entirely empty. It was at once apparent that we had to deal with the left kidney rather than the spleen. Notwithstanding the fact that the tumor was situated outside of the peritoneal cavity it had pushed the small intestines deep into the pelvic cavity and produced

ENORMOUS DISTENTION

of the vessels of the mesocolon. This was now divided by the scissors, and the edges caught with the forceps so as to guard against hemorrhage. Adhesions between the tumor and the peritoneum were broken up, and a trocar and cannula pushed into the growth. A small quantity of syrupy straw-colored fluid escaped. The interior of the growth was found to consist of a pulpy mass. The cavity was thoroughly cleansed, the other kidney examined and found normal and the wound closed. Till the seventh day the case did well. On the seventh day the temperature rose to 101.5° F., and two small abscesses were found at the insertions of the sutures. Other parts of the wound had healed nicely. She left the hospital later in a promising condition. Weight of tumor, fifteen pounds; length, $6\frac{1}{2}$ inches; depth, $5\frac{1}{2}$ inches; thickness, $4\frac{3}{4}$ inches; oval and lobulated at the upper and back and the lower and anterior parts. Surface smooth. The kidney may be seen doubled upon itself. The neoplasm sprung from the outer border and the anterior surface of the kidney at a point about two and a half inches from its lower extremity, and is continuous with it along the whole concave border to the upper extremity. The capsule of the kidney formed the investing membrane of the tumor. The centre of the tumor comprises a cavity about the size of the fist, filled with pulpy matter. The microscopic appearances of the tumor are a mass of very small spherical embryonic cells. Encephaloid sarcoma. The kidney was normal except the portion contiguous with the growth, which shows infiltration with embryonic elements.

Dr. A. W. Johnson, of Danville, Ky., discussed the feasibility of accurate diagnosis in abdominal tumors. He reported one case which Keith had been watching for nine years as a case of fibroid tumor, and on operating before a large crowd found he had a cyst of the broad ligament. The vast majority of sarcomas in children he thought to be hopeless, and disaster is certain to follow.

Dr. E. R. Palmer, of Louisville, asked what fluid Dr. Roberts had used in cleaning the abdomen. Answer, warm water.

Dr. J. G. Brooks, of Paducah, Ky., delivered the

PRESIDENT'S ADDRESS.

Medicine is the most comprehensive of all sciences; while law has to deal with the material side of our nature, theology with the spiritual aspect, and the physical sciences look upon man as a wonderful, incomprehensible piece of machinery, from the standpoint of medical science we consider and deal with all three of these conditions of humanity.

What relation, therefore, can be considered half so confidential, half so intimate, as that which exists between the physician and his patient?

Realizing the extreme delicacy of this relation we can but admire the wisdom and forethought of our wise predecessors who so well formulated the

CODE OF ETHICS.

There has arisen in New York City and State a division in the regular profession between those who adhere to and those who ignore the code of ethics of the American Medical Association. Rather than allow his pocket to suffer by obeying the code, which would not allow him to consult with the homœpathic general practitioner, the regular specialist cries "Away with the code."

Another portion of our code makes it a reprehensible practice for a man to

ADVERTISE HIMSELF

in any of the numerous ways well known to business men; yet there are not a few men who, while obeying the letter, violate its spirit by taking hold of everything new, such at the gaseous enemata treatment, the pneumatic cabinet and the like, and manage to get their names published in the daily press in connection with long articles on "The New and Certain Cure for Consumption," etc., etc., etc. What little difference there is between those men who contrive to have reporters present (without their knowledge of course) at their operations, and the advertising charlatan, may be placed to the credit of the latter, for the public may if it will estimate him at his true worth.

It is easy to define the ethics which should govern the relationship of the specialist to the general practitioner, but how few observe the rules, how many

SPECIALISTS ABUSE THE CONFIDENCE

reposed in them to win away the patients of the physician to whom he should be an aid and consultant. When a patient is sent to him for treatment for some throat, eye, or ear trouble, with which the general practitioner does not feel sufficiently familiar to battle, it plainly becomes his duty to treat that particular trouble and nothing else.

Again, there is a definite relation which should exist between

THE DOCTOR AND THE DRUGGIST.

It is clearly the duty of the latter to compound the prescription sent him by the physician, and the issue between the pharmacist and physician should be definitely settled and lived up to by both parties. I would suggest that we memorialize our Legislature to adopt a law like that in force in Illinois, which, after describing the requirements of a physician and fixing the penalty for the violation of the law, reads thus: "Any person will be regarded as practising medicine, within the meaning of this act, who shall treat, operate on, or prescribe for any physical ailment of another." The American Pharmaceutical Association is in favor of securing amicable unity of action, as was evidenced by its representatives at the meeting of the American Medical Association at Chicago. The physician should adopt the rule never to prescribe any manufacturer's medicines whatever. We are induced to recommend pills, elixirs, etc., where the exact formulæ is published, because of their elegance of preparation; but to me they are like unto ready-made clothing compared with that made to order, they may fit, but most likely they will not. Another important point is, prescriptions should be put up by well-trained hands. The dispensing of medicines should be entirely separate from everything else which goes to make up the drug store.

I must condemn in the strongest terms the practice, growing quite common, of physicians giving laudatory certificates of proprietary medicines. Whether it be deserved or not, there will always lurk the suspicion that the physician has sold his name for so many dollars.

A word as to the relations between

THE DOCTOR AND CLERGYMAN.

"Every man to his trade" is an excellent motto of far-reaching significance. With the highest respect for the ministerial calling we often find them volunteering gratuitous advice on medical subjects, which is neither to the advantage of the physician nor patient. I have observed that when we find a preacher and doctor combined, that he is generally a bigot in divinity and a quack in medicine.

In thus reviewing the field of medical ethics, I more than ever feel the true value and wisdom of the code, and my reflection convinces me that he who flavors his daily life with the essence of this code, will surely not only be a better physician, but in every sense a truer, nobler, more nearly divine man.

Dr. O. D. Todd, of Eminence, read an address on

THE SUCCESSFUL PRACTITIONER.

He thought that too many of our profession spent too much time in advertising the abilities which they do not possess, for the good of themselves, the profession, and patients. Homœopathy received its just deserts at his hands, and he likened its treatment to the hair of the dog to cure the bite of the same. When he saw one of these gentlemen swinging his shingle to the breeze, he felt like exclaiming, in the language of the sheriff, "God save the Commonwealth." He thought they were murderers, and worse than murderers. The murderer was honest in his profession, and did not pretend to be a doctor, and was liable for consequences. He thought every homœopath should be hung till he was dead three times. The doctor then branched off from the "grave" to the gay, and rolled off sentiment about the ladies till he could hardly hear himself for the applause he created.

A communication was received from the State Pharmaceutical Society, asking the combined effort of the two societies to procure the passage of a law making doctors' and druggists' bills preferred claims.

Dr. W. W. Cleaver, of Lebanon, introduced a resolution which had for its object the removal from the Governor of the power to appoint superintendents of the insane asylums of the State, as this made it

A MATTER OF POLITICS,

and subject to change, and demanded qualifications more those of a politician than a scientific man. Our late Governor, Dr. J. Proctor Knott, appointed two little-pill men on the State Board of Health, which board of health was called into existence by this Society. One of these two was a non-resident of the State. True, he had a little office in Louisville, but his wife lived in New Albany, Ind., and he should have slept there if he did not. The speaker was a friend of the present Governor, and had brought his name before the county in which he lived, but he could not indorse his actions in regard to medical appointments. The Governor requested the resignation of the superintendent of the Anchorage Asylum at Louisville, a gentleman who had been long and faithfully in the harness. Such a storm of public indignation arose that the Senate would not have confirmed the nomination, and the Governor was compelled to withdraw his request. No sooner, however, had the Legislature adjourned, gone home, and

KISSED THEIR WIVES AND HUGGED THEIR BABIES,

than the superintendent was informed that his successor had been appointed, but if he wished he could have a few days in which to resign. He, of course, resigned. The Governors may not be so much at fault, but they have friends who are persistent in their demands for favors, and must be satisfied. The doctor closed with an eloquent appeal to take the appointments of medical offices out of the slums of politics. His speech was greeted with rounds of applause. The President appointed as a committee to push this matter, Drs. Cleaver, Rodman, Matthews, and Palmer. Dr. Palmer declined, saying that he could not stand Frankfort whiskey. Dr. Yandell was appointed, who declined, saying that he had his share of legislatures, and he proposed to keep clear of them for the rest of his life.

Dr. J. N. McCormac, of Bowling Green, reported progress from the committee appointed to secure legislation concerning empiricism.

A communication from the

WOMAN'S CHRISTIAN TEMPERANCE UNION

was presented. A motion was made to refer it without reading. This was supplanted by one to refer it to the board of health. Then a motion to have it read was put and lost, and it was finally referred to the board of health. Dr. Yandell, who made the motion to refer, wished to say that he intended no insult to prohibition or to any woman. Several gentlemen spoke slightly commendatory of the object of the ladies, but took care to state positively that they were not temperance men.

This discussion on temperance was followed by a very

INTEMPERATE EXHIBITION OF MEDICAL POLITICS.

There are factions in medicine in Kentucky as well as elsewhere, and when the report of the Nominating Committee was brought in, there was war almost to the knife. The chair was unable to decide on the vote on the adoption of the committee and a rising vote was called, and this was followed by the calling of the roll. The result was the rejection of the report of the committee by a vote of 26 to 29, followed by loud and prolonged cheers. The President felt affronted at the unprecedented action of the Society in rejecting the nominations of the committee, which was of his own creation, and refused to appoint another. After considerable discussion the matter was referred to the committee to report again. The committee after six or eight hours came together, held a short session, and reported to the Society the very same names for officers it had proposed before.

Motion was made to adopt the report of the committee, and was passed by a roll-call vote of 26 to 19.

Dr. Yandell rose to a question of privilege, and in a very bitter speech, in which he accused members of holding office above that which was higher than honor, offered his resignation.

Dr. William Bailey, of Louisville, offered his resignation as First Vice-President. Accepted.

Dr. John G. Cecil, of Louisville, offered his resignation of the office of Treasurer, which was accepted. Several gentlemen rose to a question of privilege, some acrimonious remarks were made, and matters began to look rather fiery in this

"DARK AND BLOODY GROUND;"

but some gentleman was thoughtful enough to call for the resumption of the order of the day, and it was done.

The trouble dates way back in feuds for which this State is so noted, and has grown into fights between college faculties. Louisville, like other cities, has three times as many medical colleges as she can stand, hence bitter rivalry and disgraceful quarrelling. The report of the Nominating Committee was adopted, and the following

OFFICERS ELECTED:

President, Dr. L. S. McMurtry, Danville; First Vice-President, William Bailey, Louisville; Second Vice-President, B. W. Stone, Hopkinsville; Permanent Secretary, Steele Bailey, Stanford; Assistant Secretary, S. M. Letcher, Richmond; Treasurer, John G. Cecil, Louisville; Librarian, T. B. Greenly, West Point; Censors, H. Brown, Houstonville; H. B. Evans, Riley Station; F. H. Clark, Lexington; Chairman of the Committee of Arrangements, J. M. Foster, Richmond, with authority to fill vacancies. Richmond was chosen as the next place of meeting, and the date the second Wednesday in May.

An amendment to the by-laws was offered, taking from the President the appointing of the Committee on Nominations, and making it to consist of one from each county represented and four from Jefferson (Louisville).

Dr. J. M. Matthews, of Louisville, made the

REPORT ON DISEASES OF THE RECTUM.

In fissure not involving the sphincter he used cocaine, one-half grain, sometimes more, dissolved in water and injected with the syringe. The discovery of rectal pockets of pus was something which he mentioned only to denounce. The regular profession does not accept this. Homœopaths are accepting it and making much money by removing these pockets. It is needless to say that it is the regular anatomical tissue that they remove, and serious results, viz., hemorrhage, may follow. At the last meeting of the American Medical Association Dr. Goodell read a most interesting paper on "The Nervous Rectum." I read a similar paper before this Society ten years ago. Laryngologists tell us of rheumatism of the throat, and I believe there are cases of rheumatism of the sphincter ani, and I have had the symptoms to clear up under rheumatic treatment. The injection of a drachm of glycerine into the rectum is generally followed by a stool in eight to twelve minutes, and forms a satisfactory new method of moving the bowels. That it would overcome constipation I hardly am ready to believe.

Dr. J. G. Carpenter, of Stanford, had been himself a subject of spasmodic stricture of the rectum, and assured the Society that death itself had no greater horrors. A tube has come into use by which you can wash out the rectum without changing the position of the patient to the upright during operation. It is quite an advantage.

Dr. A. R. Jenkins, of Louisville, thought that Dr. Matthews had laid too little importance on the injection of

CARBOLIC ACID IN PILES.

There are different piles. In some the ligature is best, in others the clamp should be used, and in still others the carbolic acid should be injected.

Dr. William Cheatham, of Louisville, made the

REPORT ON LARYNGOLOGY.

He discussed the subjects of local treatment of laryngeal tuberculosis, total extirpation of the larynx for cancer, and intubation. He thought there were, no doubt, some cases of primary tuberculosis, but they were few. We are still in want of a cure, yet local palliative treatment is incumbent on every practitioner. Lactic acid acts well on superficial ulcers. Twelve to twenty applications, or frictions of lactic acid, may cause cicatrization. Many claim to cure laryngeal phthisis, and why not, since pulmonary phthisis is sometimes cured. Intubation, in his opinion, has been the greatest advance in laryngology. All accidents may be avoided by care. He reported a case which he intubated last January.

The German Crown Prince case then came in for a share of discussion. Patrick Herron Watson, of Edinburgh, was the first who did the operation of total extirpation for cancer of the larynx. In one hundred and three cases of excision for cancer forty died within a short time of the operation.

Dr. M. F. Coomes, of Louisville, thought there must be some difference in the malignancy of the cases of Dr. Cheatham, for he reports a saving of one out of fifteen cases last year, and four out of nine this year. He thought the disease in the former year much more malignant. He did not think tracheotomy, unless done early, was of much use. If obliged to confine himself to one remedy in laryngeal phthisis he would choose iodoform. The Crown Prince's life had been prolonged, according to statistics, beyond that obtained by extirpation. I think the greatest length of life is obtained by judicious treatment. The best and lightest tubes are those made of aluminium.

Dr. Larrabee, of Louisville, said that in comparing the two operations they seem to

SCORE ABOUT THE SAME MORTALITY.

We have heard to-day points in favor of intubation, but in favor of tracheotomy we have not heard so much. Dr. Jacoby has attained remarkable results in tracheotomy by operating early. Our operations are too late. Jacobi advocates the operation as soon as the voice is lost. I would not do this, for it may be lost from other causes; but as soon as supra-clavicular breathing—so-called bellows-breathing—appears, it should not be delayed one moment.

Dr. J. H. Letcher, of Henderson, said that intubation was the best operation to begin with. It is much easier to obtain the consent of the family, as there is no hurrah and bloodshed. He reported a case where a child recovered without an operation, but generally we must operate early.

Dr. S. G. Dabney, of Louisville, thought the difficulty of feeding a very serious one. He preferred cocaine in laryngeal phthisis.

Dr. Cheatham said the child should be fed with the feeding-bottle, holding the child's

HEAD LOWER THAN ITS HEELS,

and the food then cannot run down the trachea. Wraxham and O'Dwyer had made tubes with artificial epiglottis, and report better results. He had not tried them as yet.

Dr. M. F. Coomes, of Louisville, read a paper on the improvements in instruments in

NASAL SURGERY,

and exhibited many of the instruments.

Dr. Ap Morgan Vance, of Louisville, read a paper on

THE EXPLORING NEEDLE IN BONE DISEASE.

He had been using this instrument as a means of diagnosis for the past ten years with no bad results. A patient of his recently fell into the hands of a prominent Cincinnati surgeon, who condemned the practice in the strongest terms. He brought the subject before the Society to elicit discussion, and asked, Did the needle do any harm, and if so, what? If the bone is healthy, the needle will not go farther than the periosteum; if diseased, it will certainly not make matters worse.

A number of gentlemen had used and recommended the needle, but acknowledged it to be strictly a Louisville practice.

Dr. D. W. Yandell, of Louisville, thought that the real advance all along the line in medicine and surgery was that "we are revising old methods, testing new, and trying to hold fast to the best." He favored the use of carbolic-acid injections for hemorrhoids, and added to any treatment of hemorrhoids dilatation of the sphincter.

Dr. W. A. Rodman, of Louisville, used carbolic-acid injections twenty per cent. to full strength. He thinks it necessary to inject deeply to get away from the mucous membrane, which is the only danger.

Dr. Matthews had condemned this method twelve years ago before this Society, and he still holds the same opinion. He is unable to find it mentioned by any of the authorities save a few, and by them but to be condemned. He thinks it a dangerous practice.

Dr. Yandell said he knew of two cases of death from hemorrhage after the ligature in Louisville, one of tetanus and two of peritonitis. Sloughs occur often in ligature clamps and excision, as well as after the injection of carbolic acid.

Dr. L. S. McMurtry, of Danville, read a paper on

ABDOMINAL SECTION FOR PERITONEAL INFLAMMATION.

He reported a case of a lady aged sixty years, who had had six children and good health till the past year. Five months ago she noticed an enlargement of the abdomen and all the symptoms of an ovarian tumor. Operation showed a case of encysted dropsy, and the peritoneum studded with tubercles. Many cases of peritoneal dropsy, he thought, could not be distinguished from ovarian tumor before incision. Abdominal section and drainage are of extreme value in pelvic inflammation. He reported another case of a section for peritoneal inflammation. Peritoneal inflammation has but one treatment, abdominal section and drainage done early. This is much superior to opium and euthanasia.

Dr. A. M. Cartillage, of Louisville, thought that section and drainage would not cause permanent cure. He thinks it will be of interest to wait and to see if the tuberculosis does not return.

Dr. W. H. Wathen thought it had been demonstrated beyond a doubt that abdominal section was the proper treatment. It appears now to be quite successful. He called attention in emphatic language to the growing tendency in the profession to

OPEN THE ABDOMEN.

Guarded by a correct diagnosis and good judgment, it is the glory of the profession. It is often cut open by persons unacquainted with the pathology of the abdomen, its anatomy, or the minutiæ of the operation, as well as unprepared for it. The question is to know when to open the abdomen, how to do it, and how to deal with the pathological specimens found therein. In hysterectomy the pendulum has swung just as far in the wrong direction as in the other case.

Dr. A. Morgan Vance, of Louisville, said he thought three out of five cases were not diagnosed before the beginning of the operation, which was, at the outset, really an exploratory incision. He thought that the peritoneum belonged as much, or more, to the general surgeon as to the gynecologist.

Dr. E. R. Palmer, of Louisville, made the report on

PROGRESS IN GENITO-URINARY SURGERY.

He discussed sterility in the male and female due to gonorrhœa, and said, as did numbers of gentlemen in the discussion, that he had seen repeated cases where women, after gonorrhœa, bore children. He had accidentally come upon an antiseptic and anæsthetic fluid. He had prescribed salol and carbolic acid. His salol dissolved, and, as a result, he had a very nice lubricant for the sound, etc. He used a stronger oil, consisting of salol, 360 grains; carbolic acid, 60 grains; olive oil, 6 drachms. Weaker oil: Salol, 120 grains; carbolic acid, 20 grains; and olive oil, 6 drachms.

An interesting report on Pediatrics was read by **Dr. J. A. Larrabee**, of Louisville, and a Report on Obstetrics in Dublin, by **Dr. E. S. McKee**, of Cincinnati.

Abernethy as an Advertiser. — Advertising doctors are by no means modern developments. The celebrated surgeon Abernethy, and others of his day, were regular advertisers in *The Times*, and even earlier still the announcements of regular physicians were to be met with in the public press.—*Hospital Gazette.*

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, May 23, 1888.

W. P. Northrup, M.D., President, in the Chair.

Dr. Biggs reported from the Committee on Microscopy that the lung showing a red and white mottling, presented at the meeting of April 25th, was the seat of a combined lobar and broncho-pneumonia, the red coloration being due to the lobar pneumonia, and the white showing through being the infiltrated walls of the bronchi.

The President presented, on behalf of candidates, two specimens, one showing a fracture of the ulna, and the other, abscesses of the mammæ in a child.

The President also presented, for Dr. Frank W. Hopkins, of Fishkill, N. Y., specimens showing

TUBERCULOSIS OF THE LYMPHATICS, ULCERS OF THE COLON, AND CROUPOUS COLITIS AND NEPHRITIS.

A female child, eight and a half years of age, had conjunctivitis, was listless and anæmic, and apparently quite sick. For a time she improved, but about three months before death she began to have elevation of temperature, and occasional chills and sweating. For more than a month before death she began to emaciate, albumin and casts appeared in the urine, and diarrhœa developed. For a time the treatment seemed to be of some avail, and her general condition improved, but her temperature again became elevated, there was tenderness over the spleen, enlargement of the liver, with moderate jaundice. No albumin was present at this time, but abundant hyaline and granular casts. Continuing in this condition, she gradually failed and died.

On autopsy numerous submaxillary and cervical glands were found to be enlarged, cheesy, and diffluent in their centres. The bronchial glands were moderately but uniformly enlarged, and all cheesy. There were no tubercles in the lungs, and no consolidation; only bronchitis and moderate congestion. The mesenteric and retroperitoneal glands were uniformly enlarged and cheesy, though no discrete tubercles could be found in the adjacent tissues, peritoneum, or diaphragm.

The kidneys were the seat of chronic nephritis. One was larger than the other. The markings were indistinct, the capsule adherent, and the cortex showed cicatrices. No tubercles were found within or upon either kidney.

The most marked lesion of the viscera was within the colon. At the cæcum, and about eight inches from it, upon the ascending portion of the colon, were two large ulcers extending entirely round the inner surface of the gut, and two and a half inches in breadth. When laid open, the wall seemed to have been ulcerated over nearly a square area. The lower or cæcal ulcer was limited on its upper margin by a narrow linear groove running transversely around the gut. The second large ulcer was limited both above and below by a similar narrow groove or sharp linear ulcer. These limiting grooves were large enough to allow an ordinary lead-pencil to lie in them. The edge toward the main ulcer was deeply undermined and overhanging and ragged, while the edge facing outward was clean cut. As for the main ulcers, they were honey-combed. A probe passed easily in a winding course beneath the undermined mucous membrane.

These two tubercular ulcers consisted, then, of undermined mucous membrane, limited on the margins by linear ulcers having one—the inner—edge overhanging, and the outer sharply cut, or punched out. The remaining mucous membrane of the colon was the seat of croupous inflammation, having upon its swollen and congested surface a shreddy layer of fibrine. The jejunum and ileum were the seat of catarrhal inflammation. Liver and spleen showed no tubercles, and the other viscera were normal.

Dr. H. M. Biggs presented a specimen of

PRIMARY TUBERCULOSIS OF THE UTERUS AND TUBES.

The clinical history was imperfect. The patient had had hectic fever and was supposed to be phthisical. At the autopsy the uterus was found to be about the size of an orange, and to contain considerable cheesy pus. Its walls were about the thickness of the walls of the bladder. Both the uterus and the tubes exhibited well-marked lesions of advanced tuberculosis, and there were tubercular ulcers in the vagina. There was also present recent tubercular inflammation of the peritoneum and pleura.

A second specimen was one of

THORACIC ANEURISM,

which was especially interesting because of its large size and from the absence of symptoms directing attention to its presence during life. The patient was a helper in Charity Hospital and had died suddenly. He had had no symptoms pointing to heart trouble. At the autopsy a large aneurism was found filling the whole of the mediastinum and a large part of the pleural cavity. It contained a clot, six inches in diameter, composed of laminated fibrine. The aneurism was not ruptured, and the cause of death was not clear.

A third specimen was one of

DERMOID CYST OF THE KIDNEY.

One kidney was of large size and normal in appearance; the other was small and contained six or seven cysts varying from the size of a pea to that of a filbert. The cysts contained fatty, pasty matter, composed of cholesterin crystals, fat-globules, epithelium, and compound granular corpuscles.

Dr. Biggs also presented a fourth specimen, of

MULTIPLE SOFTENING OF THE BRAIN,

which was remarkable on account of the large number and extent of the spots of softening. The brain was from a man who had been demented, but had always been able to be around. He was found one morning unconscious in bed, and so remained until he died. At the autopsy two large cysts were found in the frontal lobe on the left side, and one in the right frontal lobe. In the parietal and occipital lobes the convolutions were atrophied, and numerous small spots of softening—ten or twelve in all—were found scattered throughout the convolutions.

Dr. Boldt, referring to the first specimen presented, asked what symptoms were present, and what reason the speaker had for supposing that the tubercular process was primary in the uterine appendages.

Dr. Biggs said that there had been no symptoms of uterine disease. He had assumed that the tuberculosis was primary in the tubes rather than in the uterus, as that was more commonly the case. Primary tuberculosis in the uterus, extending thence to the tubes, was a very rare condition. The lesions in the tubes and uterus gave proofs of being so much older than those in the peritoneum and pleura that it was evident that the process had begun in the former.

The President stated that the specimen of ulcerative colitis, presented for Dr. Hopkins, had been preserved for six weeks in a solution recently prepared by Dr. Prudden for preserving specimens in gross. It had been found to be very satisfactory in its action. The solution would be presented and its composition described at the next meeting of the Society.

Dr. Francis Delafield then showed with the lantern a series of photo-micrographs illustrating the lesions of

ACUTE BRIGHT'S DISEASE.

He said: "I have been invited to demonstrate to you this evening some micro-photographs and drawings which illustrate the lesions of acute Bright's disease. But before doing this I must occupy a little time in telling you what it is that I wish to demonstrate.

"In considering the lesions of any part of the body there is a manifest advantage if we are not obliged to look upon them as morbid changes peculiar to that part of the body, but rather as changes of the same kind that we find elsewhere. This we can do as regards the lesions of acute Bright's disease.

"In many parts of the body we find what is called acute exudative inflammation—a morbid process in which the active share is taken by the blood-vessels. The serum, fibrine, and pus-cells which belong to this inflammation are derived from the contents of the blood-vessels, while changes in the tissues themselves are absent or of secondary importance.

"One of the ordinary forms of acute Bright's disease is such an exudative inflammation of the kidneys,

ACUTE EXUDATIVE NEPHRITIS.

Such a nephritis occurs as an idiopathic inflammation, and as a complication of scarlatina, diphtheria, and many of the infectious diseases. The products of inflammation, albumen, casts, pus-cells, and blood are regularly present in the urine. The excretory function of the kidneys is more or less interfered with; there is fever and prostration; there may be added anæmia, cerebral symptoms, and disturbances of the circulation.

"In the simplest examples of this form of nephritis we find, after death, no changes in the kidneys. The inflammatory products have all escaped with the urine, and no evidences of the inflammation are left. More frequently more or less of the inflammatory products remain in the kidneys, and we find, after death, cast matter, coagulated matter, and white and red blood-cells in the tubes, and white blood-cells and serum between the tubes.

"Still further than this there may be changes in the renal epithelium and in the glomeruli. The epithelial cells may be swollen or broken down, or detached from the walls of the tubes. The cells which line the capsules of the glomeruli are swollen, those which cover the capillaries and are situated within them are increased in number and size. Such a nephritis is essentially a transitory lesion. If the patient does not die from the immediate effects of the disease, the kidneys return to their natural condition.

"Secondly, we find that persons who have taken poisons such as mercury, arsenic, or phosphorus, or who have suffered from the infectious diseases, regularly exhibit changes in the cells of the viscera. These cells are simply swollen, or are infiltrated with fat, or die. How far such changes are degenerative or inflammatory is not yet definitely determined.

"In these ways are produced the second form of acute Bright's disease,

ACUTE PARENCHYMATOUS INFLAMMATION OR DEGENERATION OF THE KIDNEY.

Such a lesion is always secondary to one of the causes just mentioned. The urine is unchanged, there are no renal constitutional symptoms. But if the changes in the renal epithelium are decided and rapidly developed there will be added changes in the blood-vessels of the kidneys, albumen and casts make their appearance in the urine, and the quantity of the urine is diminished. After death we find the renal epithelium swollen, or fatty, or necrotic. In some cases the vessels are congested, and there is cast matter in the tubes.

"Thirdly, we find in different parts of the body inflammation, with the production of new connective tissue, and such inflammations are apt to persist. So we find as the third form of acute Bright's disease a condition which we may call

ACUTE DIFFUSE NEPHRITIS.

Such a nephritis is often idiopathic, it complicates scarlatina, diphtheria, and pregnancy. The urine with such a nephritis contains large quantities of albumen and casts. The patients exhibit anæmia, dropsy, cerebral symptoms, and marked disturbances of their general health. After death we find in the kidneys the same changes as are found in exudative nephritis, but, in addition, a growth of new connective tissue and of the capsule cells of the glomeruli.

The growth of new connective tissue begins in the cortex and follows the lines of the larger vessels. Its arrangement is often in the form of regular wedges. The growth of the capsule cells is often enormous, so that the tufts are compressed and finally atrophied.

"The lesions are permanent lesions, and when they have once begun their natural tendency is to continue until a large part of the kidney is replaced by new connective tissue, and a large number of the glomeruli are atrophied."

The speaker then made a lantern demonstration of the changes in the kidneys which he had described.

On motion of Dr. J. C. Peters, a vote of thanks was passed to Dr. Delafield for his interesting demonstration.

The President referred to the cases, not infrequently met with in autopsies upon children, whose urine had contained albumen and casts, where at post-mortem absolutely nothing abnormal was to be detected upon the closest examination in the kidneys.

These cases seemed to be most satisfactorily explained by the classification described under acute exudative nephritis in which the lesion is of the blood-vessels, and the exudative products are washed away in the urine.

The Society then went into executive session.

Correspondence.

HOSPITAL NOTES IN BOHEMIA.

To the Editor of The Medical Record.

Sir: Stephan's Hospital, in Reichenberg, not only provides hospital accommodation for this city, but also for a large surrounding district. Indeed, no large hospital is nearer than Prague, five hours distant by train. Situated in the centre of a thickly settled industrial district where the tall chimney of the factory is ever in sight, many cases of surgical importance present themselves, especially those resulting from injuries received from machinery, or those due to the depraved system of the European factory workman. Here, also, is a large gynecological department where almost every conceivable operation in that line is performed.

Without referring to the numerous amputations, resections, etc., which differ in no respect from our own procedures, I would call attention to certain plans of treatment that may be not without interest to the profession at home.

In the first place, chloroform is the only anæsthetic that is used here, and while not a case has ever been lost from its effects, the article employed seems to possess no advantage over ether. It takes about as long to produce narcosis, and vomiting is just as apt to occur, while the after-effects are no less unpleasant.

To prevent vomiting, Güsenbauer, of Prague, upon the first appearance of such a disposition, applies ammonia to the nostrils, to inhibit the reflex act; sometimes it does and sometimes it does not. It is, however, worthy of trial.

A simple and effective operation is that for bunion. The Vienna surgeons hold that the characteristic deformity is caused by the sesamoid bone slipping from the tendon of the flexor brevis hallucis between the first and second phalanges, thus crowding out the base of the first phalanx.

The operation is simply an incision between the bases of the great and second toes on the plantar surface, and the removal of the sesamoid. The deformity then disappears, and the wound is treated on general principles.

Amenorrhœa in plethoric young women of normal development is sometimes treated by the insertion into the cervix uteri of a small plait of spun glass. This is left in place several days, and by its irritation brings on a catarrh which results finally in menstruation. Usually the treatment must be repeated from time to time before success is achieved.

For endometritis, we use local application of iodine; but when bleeding from the granulations in the uterus is annoying, we dilate the cervix with Fritsche's steel dilators, and scratch out the uterus thoroughly down to the muscular tissue with a curette.

I cannot too highly praise the dilators referred to. They are simply steel sounds of graduated sizes, and can be introduced to the fundus without difficulty. In five minutes the cervix is sufficiently dilated and the operation can at once be completed. In the many cases we have had here, not a single bad effect has occurred from their use, and after the uterus has been thoroughly curetted the bleeding, no matter how obstinate it had been, is checked. In no case has a peritonitis, cellulitis, or other inflammatory condition been caused. One can only realize the blessing of Fritsche's dilators after experiencing the delays and annoyances incident to the employment of the various tents. Then, too, the former are cleaner and more antiseptic.

The one thing that most impresses an American studying here is the little respect that is shown to that unfortunate organ, the uterus. To one taught to handle this organ with the greatest care this is at first stupefying, but later, when he sees the excellent results obtained, he comes to the conclusion that the success of the German gynecologists is due greatly to their lack of timidity and to their thoroughness in operative measures.

For cystocele and rectocele we have operated a great many times; for the former we used the oval denudation, and for the latter the posterior colporrhaphy of Hegar—the butterfly-shaped denudation. Of late, however, especially if the prolapse is low down or there is a partially lacerated perineum, we resort to Tait's perineorrhaphy, which has the advantage of simplicity.

Amputations of the cervix are almost as common here as in Berlin, where it is said that every woman living on Friedrich Strasse (where Martin lives) has been relieved of this portion of the uterus. It seems of little use anyway, except to furnish a seat for erosions, lacerations, etc., as after the operation the internal os fulfils every requirement, and women have no difficulty in carrying children to full term and successfully delivering them. Amputations are resorted to in cases of hypertrophy and obstinate erosions, as well as on account of malignant growths.

An ingenious operation to remedy incontinence of urine in certain cases is to cut out of the vaginal wall on each side of the urethra, and arching over the meatus a long three-sided strip of tissue, one-fourth inch in width. The denuded surface is brought together with stitches. If it does not heal by first intention so much the better, as the contraction will be greater and the urethra more compressed. Usually only one side at a time is operated upon, and if the result is not satisfactory after the first operation, the second is resorted to. I have seen cases, in which all other means had been tried in vain, improve after this operation, so that in a few weeks they could hold their water for three or four hours.

Of five cases of total extirpation of the uterus (Martin's method) per vaginam, three were successful.

In thirty-seven cases of laparotomy, the mortality was a little over twenty-five per cent., many of the cases, however, being extremely unfavorable. Included in these thirty-seven cases are five Cæsarean sections, the last of which was complicated by an immense umbilical hernia and extensive adhesions. Usually in Cæsarean sections Porro's method is employed, and it is worthy of note that in every case where the intra-peritoneal method has been resorted to the patient has died.

An interesting case, to which I was sent, occurred recently in the adjacent country.

On a Tuesday night a woman began her labor, the midwife diagnosing a shoulder presentation. A country Æsculapius, being called in, succeeded in tearing off first a leg, then an arm, and finally the body, leaving the head *in* *situ.* Upon making an examination thirty-six hours later, however, I found a rupture of the lower part of the uterus, including the cervix and upper part of the vagina, the head having escaped into the abdominal cavity, while the bowel was protruding through the vulva. I at once sent for Dr. Johanovsky, formerly first assistant to Breisky, and now gynecologist here, and upon his arrival with proper instruments, a laparotomy was performed and the head removed.

The patient was left in as good condition as could be expected—reacting nicely after the operation—but subsequently died.

Another interesting case was a dermoid cyst, as large as a goose-egg, in the rectum. This had ulcerated through from the pelvis, dragging down the broad ligament with it, which formed a double pedicle. The rectal wall had entirely healed, so that the pedicles seemed to spring therefrom. On one side of the tumor grew a tuft of black hair, five inches in length, and as thick as the finger, while teeth could plainly be felt in the tumor walls. The pedicles were ligated close to the rectal wall after some difficulty, as the tumor lay high up in the rectum, and the tumor was removed. The écraseur was not employed, as the surgeon feared hemorrhage and wished to make all secure. The tumor contained teeth, hair, and spicula of bone. A young man recently had a tumor removed from just above and a little outside of his left eye. This also contained teeth.

A case of double uterus and vagina presented itself some time ago. A communication between the uteri existed. The anterior vagina was distended with pus which welled up through this opening (as only one vagina had an external outlet) and escaped through the patulous vagina. The woman had menstruated regularly, and the pus was decomposed menstrual fluid from the second uterus. The stench from this patient was something awful; a gangrenous lung could not have improved upon it. After a most careful examination a diagnosis was reached, and the septum between the two vaginæ was slit up, allowing about a pint of decomposed fluid to escape. The mucous surfaces were stitched together and the parts thoroughly syringed with carbolized water. A perfect recovery was the result.

The absence of fibroid tumors in this clinic is somewhat remarkable. In over five thousand cases treated in the female department of Stephan's Hospital, only four fibromæ have been found.

Cancer, on the contrary, flourishes in this land, where defective food, bad ventilation, and hard labor extending through generations, have greatly depreciated the physical condition of the working classes.

The loom worked by these debilitated people causes an endless variety of diseases. The continual use of the feet as a motor causes necrosis of the lower extremities, abscesses, periostitis, and all kinds of deformities.

The habit of carrying burdens on the back causes frequent periostitis of the scapula and ribs, with consequent caries and abscess. These abscesses occur very frequently at the lower angle of the scapula.

In regard to antisepsis, well, we don't place much faith in it. The doctors say they used to try it but their results were no better than at present, and it was expensive. Cleanliness, carbolized water and oil, iodoform (which latter is being discarded on account of the recent demonstrations of the Danish Professors Heyn and Rosving that it is not antiseptic, and that micro-organisms will grow freely in it, coupled with our own suspicions in this direction on account of the repeated occurrence of erysipelas in wounds in spite of it), and sublimate form our antiseptic pharmacy.

A rather complete list, it will be remarked. Yes, but the manner of using them. Only in the female department is sublimate ever used, and the carbolized water only to syringe out wounds after an operation. The spray apparatus is never employed, and only in the gynecological clinic are the instruments placed in a carbolized solution.

And we have just as good results in the surgical clinic as in the gynecological. Indeed, only two cases have died from the effects of operations in the surgical wards in two years, and they were both hernia cases. In this period over five hundred operations, largely of a major character, have been performed.

The results in both clinics are, however, extraordinarily good, and I cannot help ascribing much of the success to the clean, pure atmosphere of this mountainous district, about 2,000 feet above sea-level.

JOHN B. HAWES, M.D.,
Assistant in the Surgical and Gynecological Departments of Stephan's Hospital, Reichenberg, Bohemia.

WASHINGTON, D. C.

THE UNINTERRUPTED GALVANIC CURRENT IN EXTRA-UTERINE FŒTATION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the issue of THE MEDICAL RECORD of July 14th, Dr. A. H. Buckmaster reports a case of extra-uterine pregnancy where the fœtus was destroyed by the galvanic current without interruptions.

I think this is an important point to make, and by reference to THE MEDICAL RECORD of February 17, 1883, a similar case will be found among several others that I then reported. These two are, I believe, the only cases recorded where the uninterrupted galvanic current alone was used. As in Dr. Buckmaster's case, pregnancy had advanced to the fourth month; the reason for using the current in the manner described was the distended condition of the Fallopian tube, and its liability to rupture under mechanical influences.

I believe that the danger of rupture by the careful use, either of the faradic or the uninterrupted galvanic current, in cases that have not advanced beyond the third month, is but slight; yet the possibility of hastening this catastrophe in attempts to destroy the fœtal life should be ever borne in mind; it is well, therefore, to emphasize this doubly-demonstrated fact, that the fœtus can be effectually destroyed by the sudden increase and decrease of the current strength, without interruptions.

A. D. ROCKWELL, M.D.

TOBACCO AMBLYOPIA.—Dr. A. R. Baker read a paper with this title before the Ophthalmological Section of the American Medical Association in Cincinnati, of which the following were the conclusions: 1. There is a toxic amblyopia due to the excessive use of tobacco. 2. The excessive use of alcohol or other toxic agents does not produce the same or a similar amblyopic condition, although by their depressing influence on the vital functions they may serve as predisposing causes. 3. Tobacco amblyopia does not usually lead to total blindness. The disease is essentially a functional one. Gross pathological changes have not been demonstrated either in the retina, optic nerve, or cerebral centres. 4. The course of the disease may result in a certain amount of failure of sight and then remain stationary, even though the tobacco habit be not entirely given up. 5. Stopping the use of tobacco will result in recovery of sight without the use of specific medication, although strychnia and tonics, by increasing the general tone of the system, may hasten a cure. The moral effect of taking something to replace the loss of the tobacco is of great value.

ANODE AND CATHODE.—A writer in *L'Electrothérapie* suggests that it is easy to remember that anode corresponds to the positive pole, and cathode to the negative pole, if one reflects that the word anode contains an "n," while the word positive does not, and cathode contains no "n," while negative does. That seems to be about as useful as most mnemonic formulæ.

New Instruments.

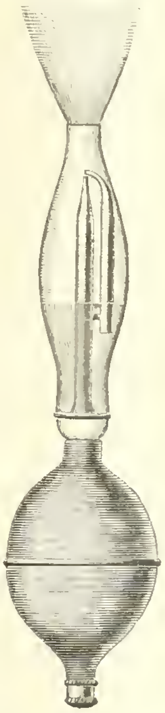
AN ATOMIZER FOR WARMING AND SPRAYING VASELINE.

By HOWARD SMITH, M.D.,

CHARLESTOWN, MASS.

The use of a spray of vaseline, either plain or medicated in various ways, has received the sanction of eminent specialists, while a convenient and altogether suitable atomizer for the purpose has remained a desideratum.

When liquefied by heat, vaseline quickly congeals at the points of the spray-tubes of the ordinary atomizer, and even what is called zero vaseline is apt to clog the instrument.



To obviate this difficulty the writer has devised the instrument figured herewith, in which ordinary vaseline or any fluid can be quickly warmed and sprayed with facility. It can be operated with one hand, leaving the other free for any purpose, and the conical extremity serves to dilate the nostril, and also protects the points of the spray tubes.

In children it may be used to spray the nasal cavities and to inflate the middle ear at the same operation, with greater facility, however, when attached to a compressed air apparatus.

It has been said of vaseline that it is only a placebo for diseases of the throat and nose, but it must be remembered that in addition to its soothing properties it is an excellent menstruum for many remedies of reputation in these diseases, such as cocaine, menthol, camphor, carbolic acid, iodoform, oxide zinc, ol. eucalyptus, and others, which in the form of spray, with vaseline, cannot fail to be thoroughly applied.

The writer can speak favorably of vaseline spray as an application to the nasal cavities, throat, and bronchial tubes, when about to be exposed to a cold, raw atmosphere. It forms a non-conducting coating to the parts, which is an admirable protection, and in our northern climate could be used on many occasions with advantage by the robust, while the delicate would find in the use of it not only comfort but safety.

In those occupations which are unhealthy from the presence of irritating particles in the air, this remedy will be found of service. There can be no doubt that the soothing properties of vaseline are increased by heat, therefore it is well to heat the atomizer containing the vaseline until the nozzle can just be borne in contact with the nostril without producing discomfort. In conclusion, the instrument here spoken of will be found useful for spraying ointments to irregular surfaces, such as the external ear, and to sensitive parts where the slightest friction is to be avoided.

A NEW EXTENSION APPARATUS.

By A. I. THAYER, M.D.,

NEWARK, N. J.

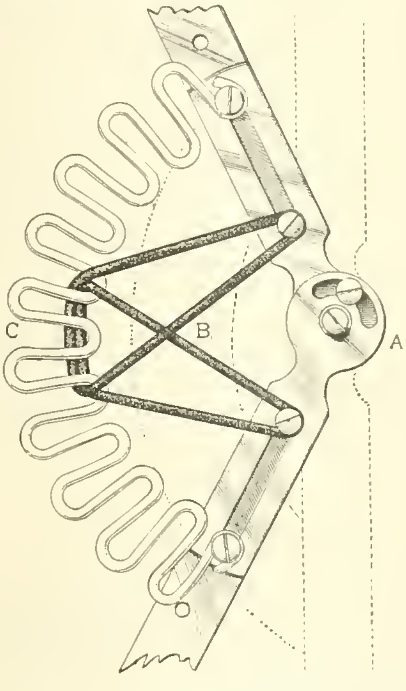
The illustration below is intended to represent an apparatus which we have devised for elastic extension of the leg, and for permitting flexion of the leg when combined with knee-joint extension.

It is presented to the profession on its merits and open to their friendly criticism. It is believed that it possesses qualifications not entirely fulfilled by other devices designed for a similar purpose, and it is hoped that on this account it may be worthy a brief description. It requires none other, for it is simple in construction, and well represented in the illustration.

That which is considered new and desirable, and hence worthy of notice, is the use of the serpentine spring (C) combined with elastic cords (B), as a means of furnishing elastic tension, which may be nicely graduated according to circumstances or changing needs by a simple change in the mode of attachment, or in the size, strength, or number of the rubber cords.

In a young child where the tension and strain are not great, the rubber rings such as are used on umbrellas will probably answer every purpose of the rubber cords. In the accompanying illustration, two of these rings are seen attached, the instrument being forcibly held, meanwhile, in a position of partial flexion.

One, two, or more of these rings may be readily attached by simply passing them over one or more of the bends in the spring and buttoning them over button-screws near and at the joints. The elastic force of these rubbers tends to resist the arching of the serpentine spring outward, and hence to favor extension of the upright bars, which are, of course, to be properly applied to the limb.



It will be seen also that the degree of flexion and extension of the leg may be strictly limited by the set-screw and slot at the joint (A). This latter neat and effective method was suggested to me by Mr. C. E. Thompson, of C. W. Thompson & Son, Newark.

There is nothing in the working of the spring *per se* to interfere with extreme flexion of the leg, and there is no awkward projection beyond the upright bars in order to allow of flexion to, or beyond, a right angle.

The special merits claimed for this apparatus are, therefore :

1. Simplicity and ease of construction.
2. Complete and ready adjustment of tension.
3. Unlimited range of motion, which may, at the same time, be effectively regulated.
4. With the above qualifications, a degree of neatness considered by wearers of instruments so great a desideratum.

It is hoped that the device may serve a useful purpose (either in its present form, or variously modified) in an important class of morbid conditions at and about the knee-joints.

Dr. Homer M. Thomas, of Chicago, has received the honorary degree of Master of Arts from the Lombard University of Galesburg, Ill.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 22 to July 28, 1888.

McParlin, Thomas H., Surgeon. Leave of absence extended one month. Par. 10, S. O. 160, Department of the Platte.

Wolverton, William D., Surgeon. Leave of absence extended twenty days. S. O. No. 142, Headquarters Division of the Atlantic.

Vickery, Richard S., Major and Surgeon. Leave of absence extended two months. S. O. 166, A. G. O., July 19, 1888.

Corson, Joseph K., Assistant Surgeon. Leave of absence for one month, with permission to apply for an extension of one month. S. O. No. 78, Headquarters Department of the Columbia, Vancouver Barracks, W. T., July 13, 1888.

Davis, William B., Captain and Assistant Surgeon, will proceed to Fort Niagara, N. Y., for the purpose of completing his target-practice for this year with Co. "C," 23 Inf. Upon completion of this duty Captain Davis will return to Fort Porter, N. Y. S. O. 145; Headquarters Division of the Atlantic, Governor's Island, N. Y. City, July 17, 1888.

Wood, Leonard, First Lieutenant and Assistant Surgeon, is released from duty at Fort Huachuca, Ariz. Ter., to take effect at the expiration of his present leave of absence, and will report to the commanding officer at Fort McDowell, A. T. Par. 14, S. O. 162, A. G. O. July 14, 1888.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 21, 1888:

	Cases.	Deaths.
Typhus fever	1	0
Typhoid fever	23	8
Scarlet fever	106	20
Cerebro-spinal meningitis	2	2
Measles	245	16
Diphtheria	118	36
Small-pox	9	0
Yellow fever	0	0
Cholera	0	0

Some Wonders of Advertising.—The extensive manner in which art is employed by modern advertisers may be judged by the fact that a certain printing firm during the month of January booked the following orders: For Pears' Soap, one million chromos of the "Dirty Boy" and the same of "Mary Anderson;" for Mother Seigel's Syrup, fifteen million chromo covers, and one million chromo box-tops; for Warner's Safe Cure, eight million chromo covers and eighty thousand show-cards; for Howell's Golden Herb Pills, one million and a half of chromo handbills; for Thorley's Food, four hundred thousand chromo covers and two-page pictures for an almanac; Kearley & Tongue require eighty thousand calendars for 1889.

"Imitative Tetanus."—Dr. Guánchez, records a case of "imitative tetanus," which occurred in a native of Caracas, a young man who had always enjoyed good health. The patient began to complain of pain in the calves of his legs, which caused him considerable difficulty in walking. There was no fever, but the pain increased, and some contraction of the flexor muscles of the leg occurred, rendering the man incapable of walking. Indeed, on the second day of the attack he could not turn in bed without a good deal of pain. He was unable to sleep, and suffered from mental anxiety. It was then elicited that his brother, who lived at a little distance, was suffering from tetanus, and that the patient, who went frequently to see him, had appeared to be greatly affected at the sight of his brother's spasmodic attacks, and had declared that he himself would die of the same malady. Dr. Guánchez, however, attributed the pains to rheumatism, which was common enough at the season when this occurred. He treated the man with anodyne liniments and jaborandi internally. No effect was produced, as intense rigidity of the legs, simulating anchylosis, came on, the patient obtaining no sleep whatever, and the pain being still very severe. A purgative was prescribed, but the trunk muscles became affected and clonic spasms began to show themselves. Bromide, chloral, narcein, and codeia were prescribed, but none of these arrested the rapid progress of the affection. The convulsions increased, opisthotonos, and lastly trismus occurred, and the man died on the sixth day. In this case the mode of invasion was different from that usual in true tetanus, which commences by affecting the muscles of the face and chest; again, there were no remissions, as in ordinary tetanus, but the disease progressed steadily and more rapidly than is usual in tetanus. As to treatment, Dr. Guánchez, who has had had some experience of ordinary tetanus, has found mercury and opium sometimes successful, and in one notable case the cure appeared to be due to the constant and careful administration of curare.—*The Lancet.*

Women and Obscene Literature.—A certain class of very good and well-meaning folk never tire of declaiming from the platform of the corrupt and licentious conduct of men, but from a recent discussion in Parliament respecting the rapid spread of corrupt literature in this country, it would appear that the male sex are not alone to blame in this matter. Indeed, were the corrupt literature business to depend on the patronage of men alone it would die a natural death. The chief customers of the vile traders in obscene publications and indecent prints and photographs are said to be women. In some parts of London there are reading-rooms and lending libraries open to females only, where young girls can have the use of private rooms, and a supply of indecent books and prints at a small charge. This is a matter which might well engage the attention of the Social Purity Association.—*London Hospital Gazette.*

The Tariff on Surgical Instruments.—The New York Neurological Society has refused to indorse the resolution of the Georgia Medical Society requesting the removal of the tariff on medical books, surgical instruments, and drugs. As the Neurological Society contains a large number of believers in tariff reduction, their action must have been dictated by the best interests of the profession. It is easy to see on what grounds they opposed this resolution, originally offered as a piece of buncombe merely. While a tax remains on the raw material the removal of the tariff on instruments discriminates against the American instrument-maker, and must ultimately raise the price of instruments. Furthermore, under existing circumstances, a surgeon who desires an instrument can have it made by a maker at his door. If the tariff on instruments be swept away without removing the tariff on raw material, the instrument-maker's trade is destroyed, and the surgeon must import his instruments. The fact that the members of the New York Society are greater importers of books and instruments than those of the Georgia Medical Society, renders their action peculiarly significant.—*Medical Standard.*

EXPERIMENTS ON SPECIAL SENSE LOCALIZATIONS IN THE CORTEX CEREBRI OF THE MONKEY.[1]

BY SANGER BROWN, M.D.,

NEW YORK.

WHEN it is remembered through what experiences any given monkey may have passed before falling into the hand of the physiologist to be experimented with, the importance will be appreciated of studying carefully the habits and characteristics of each specimen prior to operating.

For instance, a monkey fresh from his native forest, taken on shipboard and brought to a large city, might naturally be expected to be in a very unsettled frame of mind as to the nature and import of what he saw, heard, smelled, or tasted. Such a monkey might be expected to respond to the environments of civilization in a manner quite different from one which for several years, perhaps, had done duty as an organ-grinder's assistant.

The wild specimen might not have learned to associate any idea of danger with sounds which in a state of civilization are usually so associated, while the tame specimen may have been domiciled in such close contiguity to noises commonly regarded as startling, as to have acquired a certain tolerance of them. Again, in regard to taste, the wild monkey might, while in his native forest, have been forced by circumstances to accustom his palate to some root, bug, or berry similar in taste to substances which we would expect him to dislike.

In proportion, then, as the various characteristics are studied and understood, prior to operation, will the nature of the alterations produced by operation appear clear and satisfactory.

In our experiments much care and attention were given to gaining an intimate acquaintance with the various habits and preferences of each monkey prior to operation.

Some of our subjects, if very hungry, for instance, would eat a raisin quite heavily loaded with sulphate of quinine, and if less hungry, after tasting would pick such a raisin in pieces, rub it between their hands or on the floor to rid it somewhat of the quinine, and eat what remained; while other monkeys in the same cage would not eat such a raisin under any circumstances. We found no monkey which would eat a raisin loaded with quinine and a solution of acetate of strychnine.

Similarly, in regard to hearing, we found some react to noises more readily than others; but all, for some reason, showed a remarkable tolerance of the report of a pistol fired near them; even when in repose they would often fail to show any reaction, while under the same circumstances the rustling of a paper or a kissing noise was usually accompanied by a prompt bestowal of attention.

It will readily appear what erroneous conclusions one might reach if he should omit this preliminary study of each subject and proceed to compare the manifestations observed after operation with some original hypothetical standard of what a normal monkey should be.

With regard to the cortical centre, or area of vision, Munk has asserted that in the monkey extirpation of one or both occipital lobes produces persistent hemiopia or blindness. Ferrier and Yeo,[1] state that, "The only lesion which causes complete and permanent loss of vision in both eyes is total destruction of the occipital lobes and angular gyri on both sides.

"Complete extirpation of both angular gyri causes for a time total blindness, succeeded by lasting visual defect in both eyes.

"Unilateral destruction of the cortex of the angular gyrus causes temporary abolition or impairment of vision in the opposite eye—not of a hemiopic character.

"Destruction of the occipital lobe and angular gyrus on one side causes temporary amblyopia of the opposite eye and homonymous hemianopia of both eyes toward the side opposite the lesion."

Luciani[2] states that, "The visual sphere, though chiefly concentrated in the occipito-parietal zone of the hemisphere, is not clearly circumscribed therein." The same writer further states: "My new experiments confirm on the one hand the capital importance of the occipital lobes as centres of vision, . . . while on the other hand they confirm the view that these centres spread by irradiation into the parietal lobes, especially into the angular gyri."

Horsley and Schäfer[3] made four experiments in the regions of the angular gyri and occipital lobes, which they at the time thought supported the position taken by Luciani, and was intermediate between the views expressed by Ferrier and Yeo, on the one hand, and Munk on the other; but the post-mortem examinations showed that in no instance had the removal of the occipital lobes been complete.

It seemed, therefore, that further and more carefully conducted experiments were needed to set this matter at rest, and with this object in view we proceeded.

In one monkey, a small, active, intelligent Rhœsus, we destroyed as completely as we could from the surface, by the actual cautery, the gray matter of one angular gyrus. We tested the sight immediately after complete recovery from the anæsthetic, but could discover no defect of vision nor any loss of movement of the eyes or eyelids, or anæsthesia of the cornea or conjunctiva. When the eye of the same side was closed with plaster, the animal continued to see perfectly well with the eye of the other side.

No evidence of defective vision having appeared within one week after the operation, the angular gyrus of the opposite side was destroyed in the same manner as the first. This lesion was not followed, either immediately or at any subsequent time, by any visual defect that we could discover by the most careful tests we knew how to apply. This animal was kept several months and carefully examined by many people besides ourselves, and was exhibited at a meeting of the Neurological Society, held in the Physiological Laboratory of University College. That the lesion was complete on both sides was proved by the post-mortem examination (see Fig. 1).

---

[1] The experiments to which this article relates were made in conjunction with Mr. E. A. Schäfer, F.R.S., Jodrell Professor of Physiology, University College, London, in the Physiological Laboratory of that institution. The details of our observations, with representations showing the exact post-mortem condition of the brains operated upon, are given in a paper submitted by us to the Royal Society, which was read at the meeting of that Society, December 16, 1887.

[1] Abstract of paper presented to the Royal Society by Ferrier and Yeo, Brain, vol. vii., p. 139.

[2] Brain, vol. vii., p. 145.

[3] Horsley and Schäfer: A Record of Experiments upon the Functions of the Cerebral Cortex. Philosophical Transactions of the Royal Society, 1887.

In another monkey we separated the lips of the fissures bounding the angular gyrus of one side and entirely scooped out that convolution, making a deep gap in the surface of the brain. This operation was followed by a disturbance of vision—hemiopia—which entirely disappeared in a few days. No other disturbance of the visual organs could be at any time discovered as a result of this lesion, and the temporary hemiopia is easily accounted for by the disturbance of the circulation in the adjacent occipital lobe, assuming that this latter lobe is the cortical seat of visual perceptions.

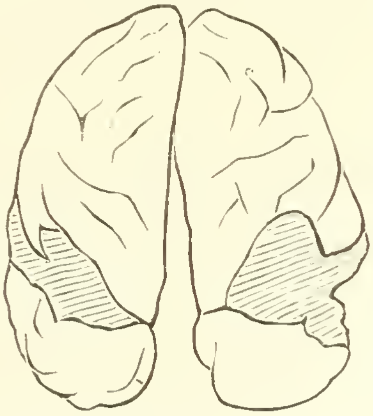

Fig. 1.—Brain of monkey, with complete destruction of both angular gyri, viewed from above.

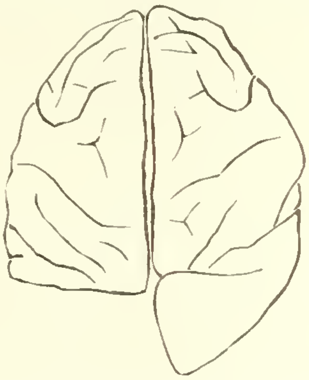

Fig. 2.—Brain of monkey, with complete removal of left occipital lobe, viewed from above.

It may be remarked, incidentally, that both of these cases oppose the statement of Professor H. Munk that the angular gyrus is related to the sensibility or movements of the opposite eyeball.[1]

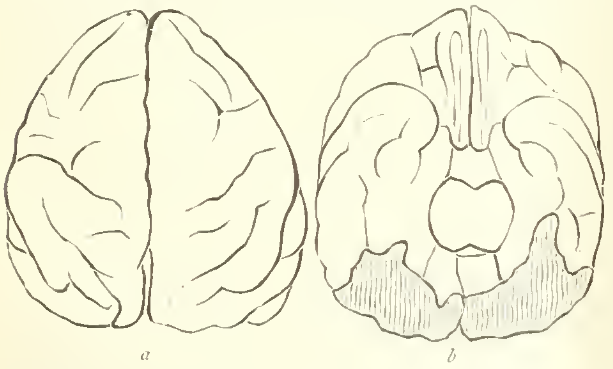

Fig. 3.—Brain of monkey, with complete removal of both occipital lobes, viewed from above in *a* and below in *b*. On the under-surface the lesion of the cortex, as shown by the shading, extends somewhat in advance of the limit of the occipital lobe.

Our experiments upon the occipital lobe have yielded no less definite positive results than those upon the angular gyrus have been negative.

In one monkey the left occipital lobe was removed by a vertical incision carried along the line of the parieto-occipital fissure. That the removal was complete was confirmed by post-mortem examination some eight months later (see Fig. 2), when the angular gyrus was found to be quite intact, the cut surface showing as clearly the distinction of gray and white matter as when the operation was performed. The result was the immediate establishment of bilateral homonymous hemianopsia, which persisted during the whole time that the monkey was kept alive. Objects so placed that their images fell upon the left half of the retinæ were not noticed. A raisin fixed to the end of a long stick held from behind, so the holder was not being observed, and then moved from right to left at a convenient distance from the monkey, was not noticed till it had passed the mesial vertical plane, when it was instantly seized and eaten; currants strewn upon the floor were only picked up toward the left side, and a threatened blow from the right side was not noticed.

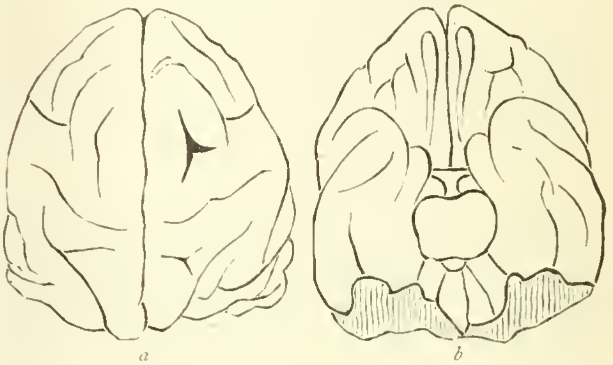

Fig. 4.—Brain of monkey, with complete removal of both occipital lobes, viewed from above in *a* and below in *b*. The lesion is not so extensive on the under-surface as the one shown in Fig. 3.

In our monkey we removed both occipital lobes at one operation (see Fig. 3, *a*, *b*). The result was total and persistent blindness. The animal could only find food by groping and smelling, and when frightened would dash headlong against whatever object happened to be in its way. Placed in a dark room, it gave no signs of perception when a bright light was flashed in its face.

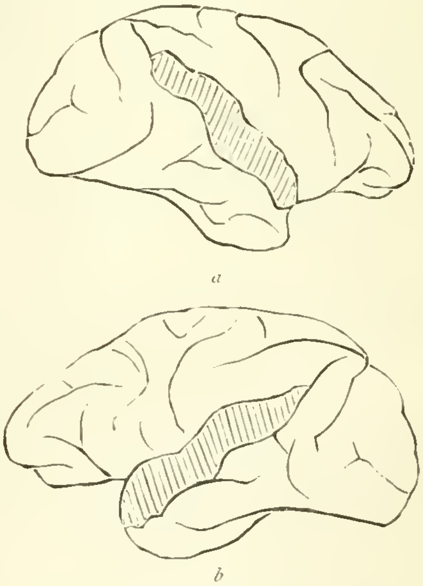

Fig. 5.—Brain of monkey, with complete removal of both superior temporal gyri. The right side is shown in *a* and the left side in *b*.

Hearing was very acute, and all the other senses besides vision appeared unimpaired. When the animal was killed, several months later, the angular gyri were found perfectly intact, and all the parts looked fresh and healthy.

Soon after the operation last described a similar operation was attempted upon another monkey of the same kind and size; but the post-mortem examination showed that in this case the lesion did not extend so far forward on the under-surface of the brain as in the former, and the animal, though entirely blind at first, after a few days appeared to have an indistinct perception of objects moved or held so as to correspond to the extreme upper and right-hand margin of the visual plane. This was only apparent when the conditions of vision were extremely favorable, for to objects placed in other positions he was as insensible as the other. All the parts were found perfectly healthy on post-morten examination several months after the operation.

---

[1] H. Munk: Ueber die Functionen der Grosshirnrande, Gesammelte Mittheilungen, 4te Mittheilung, 1878.

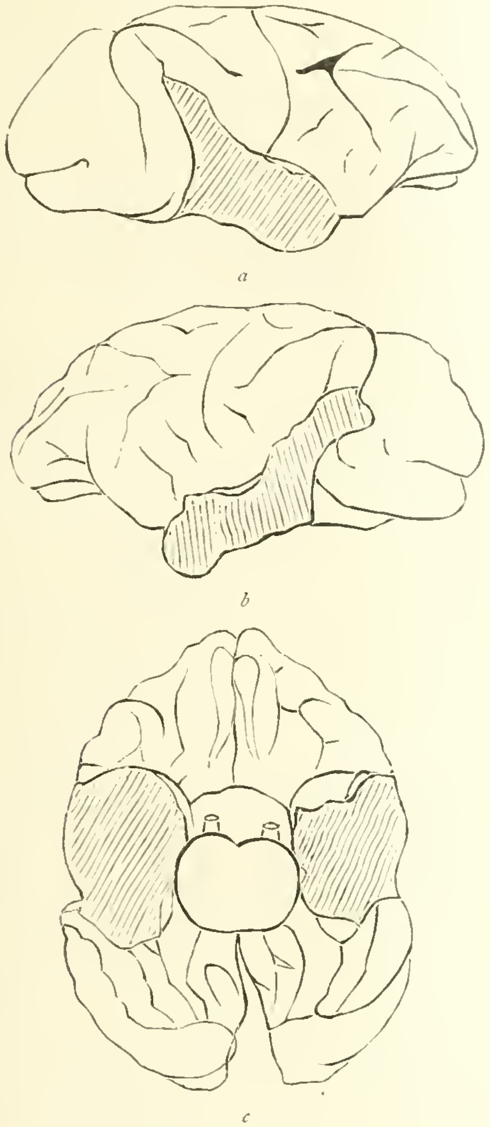

Fig. 6.—Brain of monkey, with almost complete removal of both temporal lobes, as seen from each side and below.

From these two cases it might reasonably be inferred that those experimenters in this region, who have concluded that the visual centre was not confined to this lobe, had not removed the part completely, and, indeed, Horsley and Schäfer[1] freely admit that the post-mortem examination of their cases showed that removal has been far from complete.

It should be stated that we invariably got measurements of the eyes by applying electrical stimulation to the occipital lobes.

We also made experiments upon six monkeys with a purpose of discovering the location in the cortex cerebri of the sense of hearing.

Ferrier and Yeo state[2] that "destruction of the superior temporo-sphenoidal convolution on both sides causes complete and permanent loss of hearing, without other sensory or motor defect. Hearing is not impaired by lesions of any other part of the temporal lobe."

The experimental evidence in support of the above statement appears to have been that electrical stimulation of this gyrus produced movements of the opposite ear, and that destruction of both gyri in one monkey appeared to produce deafness. As it did not appear to us that the conditions necessary to a reliable conclusion had been fairly fulfilled in this individual case, we more or less completely destroyed, in six monkeys, the superior temporo-sphenoidal convolution on both sides. In one or two instances a small shred of gray matter belonging to this convolution was found post-mortem, but as even in these the part had been deprived of the medullary centre, the removal in all six may be regarded as complete. In one large female Rhœsus we separated the fissures bounding the convolution and scooped it out to the very bottom on both sides of the brain, so that not a trace remained (see Fig. 5), and in another monkey we removed not only this convolution but the whole temporal lobe on both sides of the brain (see Fig. 6, *a*, *b*, *c*). These two, as well as all the other animals with this lesion, even immediately after the operation, as soon as sufficiently recovered from the anæsthetic, reacted to slight sounds, such as the crumpling of dry paper or smacking of the lips. These two animals with the more extensive lesions were kept alive for several months, as were some of the others, but none at any time showed evidence of impairment of the auditory faculties, or, indeed, of any of the special senses.

The case above referred to, in which the whole temporo-sphenoidal lobes of both sides were removed, is opposed to Dr. Ferrier's surmises that the special sense of taste is in the anterior part of this lobe,[1] as this animal's taste was tested in many ways, both before and after the operation, without any evidence of impairment having been discovered.

The two monkeys above referred to, in which the lesions of the temporal lobes were most extensive, presented well-marked psychical changes of a very interesting nature, which could not be fairly discussed within present limits.

Hotel Normandie, New York.

Tannin in Phthisis.—In the *Riforma Medica* of June 11th, Dr. C. De-Viti-Demarco recommends "saturation of the blood with tannin" as an effectual means of checking the development of the tubercle bacillus, and giving the organism time to eliminate it. He has recently treated two patients, in the second and third stage of consumption respectively, by giving them the drug in the following form: ℞. Tannic acid, ℨ j.; creosote, ♏ iij.; glycerine and alcohol, āā q. s. To make eight pills; one to be taken every two hours during the day. In both cases the temperature became normal after twelve days' treatment and remained so; the condition of the lungs, however, was unchanged. One of the patients, who was hopelessly ill when the treatment was begun, died in a month; but the other, though having a large cavity in each apex and extensive tubercular deposits in the left lung, was "immensely improved" after three months, having gained weight and almost lost his cough, while the expectoration was diminished to half what it had been. The prolonged administration of tannin had caused no ill effect. It is to be hoped that this plan will be further tried in less advanced cases than those reported by Dr. De-Viti-Demarco; the favorable results obtained by Professor A. Ceccherelli with tannin in local tuberculosis (see *Journal*, April 7, 1888, p. 656) seem to encourage the belief that it really has an antagonistic effect of some kind on the micro-organism causing the disease.—*British Medical Journal.*

RENAL TENESMUS:

A Result of Chronic Cystitis and Ureteritis; Successful Treatment by Kolpo-uretero-cystotomy and Intravaginal Drainage combined with Elevation and Support of the Uterus and Ovaries.[1]

By NATHAN BOZEMAN, M.D.,

SURGEON TO THE WOMAN'S HOSPITAL, NEW YORK

I READ before the New York State Medical Association, September 27, 1887, a paper entitled, "Chronic Pyelitis; Successful Treatment by Kolpo-uretero-cystotomy, Irrigation of the Pelvis of the Kidney, and Intravaginal Drainage.[2]" In this communication I showed that the vesical orifice of one of the ureters could be exposed by making an opening at the ureteral angle of the trigone of the bladder on the affected side, and that disease of the renal pelvis could be treated and cured by local means. In order to catheterize the ureter and pelvis of the kidney, the anterior wall of the vagina is exposed, in the supported knee-elbow or left lateral position, by the use of my dilating speculum and perineal elevator; the upper border of the artificial opening is then elevated by means of a tenaculum, and the vesical mucous membrane containing the orifice of the ureter is thus rolled out into the vagina. In this way we are enabled to guide a flexible catheter into the ureter. and thus to avoid all injurious probing of the bladder. By injecting warm water, or a solution of bichloride of mercury (1–20,000), through the catheter with a small syringe, the pelvis of the kidney is gradually filled. Distention of the organ gives rise to a peculiar pain, which serves as a guide as to the quantity of fluid which should be injected. When the water is allowed to escape, it brings with it pus, blood, and calcareous detritus, if these irritating substances are present. The injection should be repeated every two or three days or oftener, according to circumstances, and the irrigation continued until the washings are free from sediment.

In the paper referred to I further showed the effect of this method of treatment upon obstruction of the urethra and cystitis, which are commonly associated with the pyelitis. The opening in the bladder, by affording physiological rest and drainage of this organ and the urethra, leads to the subsidence of the inflammation or irritability of the mucous membrane of both structures, and to the atrophy of the thickened muscular walls The bladder being thus kept continually empty through intravaginal drainage, offers no resistance to the entrance of the urine as it comes from the ureters, and there is no longer a tendency to its reflux toward the kidney during expulsive efforts of the bladder. Physiological rest and drainage of the ureters and pelves of the kidneys, as well as of the bladder and urethra, consequently follow the operation. I also described several forms of intravaginal and vulvo-vaginal drainage instruments, which, by collecting the urine in a satisfactory manner and making the patient comfortable, free, in great part, the operation from its chief objections; to wit, the presence of accumulated urine in the bladder and vagina, and dribbling from the vulva.

At this time I had treated two cases of pyelitis, both of which were cured. I have since done kolpo-cystotomy and kolpo-uretero-cystotomy eight times.[3] Having thus a ready means of access to the bladder, ureters, and pelves of the kidney, I have learned, by observation and experiment upon the living subject, some new and important facts concerning the diseases of the upper urinary organs in women.

ANATOMY AND PATHOLOGY.—In presenting the results of these investigations, I have selected as my subject "Renal Tenesmus," a frequent result of chronic cystitis and ureteritis, in contradistinction to pyelitis, the usual result of urethrocele, cystitis, and ureteritis. It is the most characteristic symptom of the class of cases of which I wish to speak. I have chosen this symptom rather than a pathological condition, as I wish to make it prominent, because it is the first and frequently the only indication of the gradual extension of urethral and vesical disease to the ureters and pelves of the kidneys. From the peculiarity and wide range of the group of symptoms embodied in the use of the term renal tenesmus, it is liable to be confounded with pyelitis, with which it is closely allied. I mean to designate by this term a distinct manifestation of morbid irritability, without pathological evidences of inflammation other than that of pain. The distinction between it and pyelitis, resulting, to a certain extent, from like causes, cannot, I conceive, be too sharply drawn.

Here, as in other parts of the body, the progress of disease is inward—from organs communicating directly with the exterior of the body and exposed to injurious influences from without to those in more sheltered positions in the interior. It is true that an abnormal condition of the urine sometimes leads to the formation of renal calculi, or the ureters and pelves of the kidneys may be pressed upon by abdominal tumors, be the seat of a new-growth, or be implicated in disease of neighboring organs, and in these conditions renal tenesmus may occur as one of the symptoms; but as I have approached its study from the urethra and bladder, I will at present consider it only in its relations to disease of the upper urinary passages following affections of the urethra and bladder.

That an inflammation of the mucous membrane of the urethra and bladder should extend to the vesical extremity of one or both ureters is not surprising. The mucous membrane lining the ureters is continuous with that of the bladder, and the ducts traverse the vesical wall for an inch and a half. It is therefore probable that in an acute cystitis, preceded or not by urethritis, the vesical part of the ureters rarely escapes. As a rule, when the inflammation of the bladder subsides the ureteral mucous membrane returns to a normal condition. But if urethrocele should coexist, or the walls of the bladder should become hypertrophied, or there should be distortion of a ureter arising from the pressure upon it of a displaced uterus or ovary, or both, or of pelvic growths of any kind; why, then, the disease of this portion of the duct is not only liable to continue, but it will sooner or later extend to the pelvis of one or both kidneys, under the form of pyelitis, or of renal tenesmus just pointed out.

Cystitis more or less localized in the base of the bladder, complicated by ureteritis, is a more obscure but highly interesting condition. The cystitis commences as a local or general inflammation, and afterward becomes confined to one locality in consequence of the retention of residual urine due to sacculation of this part of the bladder. Pouches in the base of the bladder may result from irregular thickening of its muscular coat or from distortion of the vesico-vaginal septum, in consequence of the presence of cicatricial bands and contractions in the vagina, or, as I have more frequently observed of late, from fixation of the uterus in an abnormal position. There is frequently, in these latter cases, lateral displacement of the uterus, and the cervix is drawn upward and outward toward one or the other side of the pelvis, carrying the vesical wall with it and becoming there more or less fixed. In this way is produced a funnel-shaped pouch, the apex of which corresponds to the attachment of the cervix to the bladder. A fold in the vesical wall also occurs in cases of backward displacements of the uterus, especially in well-marked retroflexions with inclination of the fundus to one or the other side of the pelvis. The bladder is attached to the anterior aspect of the cervix uteri along a line about an inch in length. When the fundus uteri sinks into Douglass' cul-de-sac and the utero-vesical pouch of the peritoneum is thus effaced, the highest part of the attachment of the uterus to the bladder is drawn backward, the lowest is displaced forward by the cervix, and the superior wall of the bladder approaches the base. In this way, instead of the regular and rounded form of the cavity of the bladder, at this point is produced a more or less acute angle, the apex of which corresponds to the highest point of the utero-vesical attachment, and consequently the deepest and narrowest part, to the side toward which the uterus is inclined. Frequently, these folds and distortions of the vesical walls are very distinct, and the artificial opening in the bladder, the result of the operation of kolpo-uretero-cystotomy, affords an excellent opportunity for the study of the mechanism of their production. One of the ureters may empty into a pouch produced in some one of these ways, and thus the inflammation may extend to its lining membrane. The distortion of the bladder at this part also favors the reflux of urine into the duct during expulsive efforts. Fixation of the uterus also, even when the organ is in a normal position, by interfering with the mobility of the bladder, prevents its easy and symmetrical dilatation by the urine and the complete evacuation of its contents. These influences must be studied all the more closely, because, although great irritability of the bladder and renal tenesmus exist, sometimes there is no pus in the urine, and at others only a very small amount. Exacerbations, however, occur, especially during the menstrual periods, when the inflammation extends to the entire vesical mucous membrane and the urine contains large quantities of pus.

[3] I have now performed thirteen operations in all, combined with intravaginal drainage—two of kolpo-cystotomy and eleven of kolpo-uretero-cystotomy. Two of these operations were for urethrocele and cystitis, one was for left pyo-nephrosis with dilatation of the ureter, one for left pyelitis with sacculation of the ureter, three were for pyelitis with dilatation of the ureter, and five for renal tenesmus, without dilatation of the ureters, or pelves of the kidneys.

Ureteritis may remain localized in the vesical portion of the ureter, or the inflammation, from an increasing urethral, vesical, or uterine lesion, may extend upward and involve the pelvis of the kidneys. In my experience this extension is either preceded or accompanied by dilatation of the ducts. When I have opened the bladder and exposed the ureter, in those cases where the inflammation was confined to its lower part, the lumen of the duct was contracted in consequence of thickening of its coats or of morbid irritability in its entire extent, associated with uterine and ovarian displacements, which there is reason to believe are almost if not always present under such circumstances. In the cases of pyelitis which I have treated, on the other hand, associated also with uterine and ovarian displacements, the ureter was considerably dilated. The cause of the dilatation of the ureter and at the same time the extension of the inflammation is, as I believe, the reflux of the urine bearing septic material from the bladder, arising mainly from the increase of obstruction in the urethra to the outflow of the urine. Thickening and narrowing of the urethra, distinguishing features of urethrocele, by necessitating forcible efforts of the bladder to expel its contents, lead to concentric hypertrophy of the muscular coat and increase the strain upon the ureters, thus causing pyelitis. Partial or general thickening of the muscular fibres of both these structures, the result of overaction in irritable bladders arising from recurrent attacks of cystitis, produces the same effect by increasing the power of the contractions of the bladder. At the same time these contractions occur with greater frequency and longer duration, thus leading to renal tenesmus, as I have observed it in connection with the various forms of uterine and ovarian displacements just described.

CLASSIFICATION.—Now, from the foregoing anatomical and pathological considerations, the chronic inflammatory affections of the female urinary passages may properly be divided into four classes, namely: 1, Urethritis; 2, cystitis; 3, ureteritis; 4, pyelitis. The progress of development is from without inward, and the order of occurrence, as I believe, is the one enumerated.

URETHROCELE AND CYSTITIS.—The following extract from a paper[1] I read before the Medical Society of the State of New York, will show the scope of my views upon urethritis and cystitis at that date, and will serve at the same time to connect these views with those I at present entertain upon the pathology and treatment of the chronic inflammatory diseases of the upper urinary passages belonging to the third and fourth classes of our division, namely, ureteritis and pyelitis, to be discussed further on.

"The starting-point of urethral and vesical lesions in the female is to be sought in the lower half of the urethra, closely related in front with the triangular ligament and blending behind with a spongy erectile tissue of the vagina.

"The calibre of the urethra may be transiently narrowed by congestion of its mucous lining, or permanently narrowed by infiltration of coagulable lymph into the underlying cellulo-elastic tissue, which constitutes properly the so-called organic stricture, as in the male, and which, however seldom met with, is liable to the same sequences.

"Infiltration into the spongy erectile tissue outside the urethra, by plastic lymph, is, I believe, by far the most common beginning of the morbid process, whatever be the cause that produces it. This interrupts the stream of urine, either by encroaching on the calibre of the urethra, or by deflecting it beneath the triangular ligament, both cases being attended with more or less dilatation above.

"The next step in sequence is increased functional activity of the urethral muscular coat in overcoming the obstruction to the flow of urine. The result upon its structure is hypertrophy, and this will be of the eccentric type, thickening the urethral walls, while enlarging the calibre. Hence the ease with which large catheters of a proper curve pass at all stages of the disease. False and true hypertrophy here coexist. The true hypertrophy increases *pari passu* with the muscular contraction, and is followed by still greater distortion of the canal at an angle more and more acute as it turns the triangular ligament, and with corresponding contraction of its walls at that point. This mechanical impediment below coincides with the increased weight and volume of the stream of urine above, to put the walls of the urethra on the stretch in the upper part of its course.

"Thus is gradually formed the urinous tumor, which drags down in front the adjacent vaginal wall, appearing as a prolapsus between the nymphæ, and filling up the ostium vaginæ.

"The looser attachment of the urethra to the vagina in the upper part of its course facilitates this result. Such is the condition of the parts to which I apply the term *urethrocele*.[2] Often confounded with cystocele, it is really distinct.

"The arrest and retention of but a few drops of urine, at first, goes on until this may amount to a teaspoonful or more. It is then decomposed in this pocket, becomes alkaline, and by its irritation provokes congestion of the urethral mucous membrane. This congestion, extending to the vesicle trigone above, will bring white glairy mucus into the urine with vesical and rectal tenesmus. Causes favoring this extension are errors in diet, overexertion, and excessive coition. Acute cystitis resulting, first complicates the urethrocele, and is more or less decided according to the gravity of its determining cause. After a few days the active congestion disappears or subsides, with the vesical symptoms, leaving the urethrocele persistent. A few days, or weeks, or months afterward, similar provoking causes, even slighter than at first, will reproduce the congestion, while extending its area, with a corresponding increase of the severity of all the symptoms. . . . Finally, chronic cystitis overshadows the primitive urethrocele, although this still contributes to exacerbate the long and frightful train of evils.

---

[1] Urethrocele, Catarrh, and Ulceration of the Bladder in Females. See Transactions for 1871.

[2] Urethra and κηλη, a mongrel of Latin and Greek. This word, in the absence of any other to designate the lesion named, I coined and first employed in the description here copied. There is no evidence of the use of this word by writers prior to the date of my paper. Still, recognizing the appropriateness of its first employment, I have used it in this paper in the same sense, believing it to be in strict harmony with the words cystocele and rectocele, and with my present study of the subject.

"The vesical mucous membrane seems to possess almost boundless susceptibilities of irritation, and the higher this ranges, or the greater the area congested by contact with ammoniacal urine, the more is the subjacent muscular coat excited to contractions of abnormal force and frequency. Hence hypertrophy, increased congestion, blindly seeking relief by increased mucous secretion, and more active fermentation of the urine, deposits of its ammoniacal magnesian phosphate, sometimes hemorrhage into the bladder, blood extravasated into the submucous cellular tissue, or abscesses formed there.

"This hypertrophy of the concentric type, although apparently slight in the mucous coat, is more serious in the muscular coat, whose efforts to overcome the urethral impediment and rid the bladder of its acrid contents, keep it growing until it reaches an inch or more in thickness. Autopsies reveal upon its inner surface fascicles of muscle like the interior of the right ventricle of the heart. Its color is deepened by the increase of venous blood in its retarded circulation, and its consistence softened by the same cause. The circular and spiral muscular fibres of the upper urethra are also hypertrophied and overcome the former dilatation of the canal, thus converting the eccentric into concentric hypertrophy of the urethra, which has become firmer to the touch, while its urinous tumor is less defined. . . .

"From the earliest period of vesical hypertrophy, the congestion of the mucous membrane occasions thickening with an œdematous feeling in the bas-fond, and the contraction of its pliant walls under this irritation is even greater than is possible after they have been straightened out and expanded by progressive thickening. The vesical cavity, moreover, is reduced by the pressure of the anteverted womb upon its superior fundus, which at this early stage gives it a somewhat cylindrical shape.

"On the vagina, the effects of a hypertrophied bladder are seen in the increased firmness of the vesico-vaginal septum, and the congestion and hyperæsthesia of its mucous membrane.

"Ulceration initiates the destructive stage of subacute inflammation or chronic catarrh of the bladder. It will be superinduced by the excessive hyperæmia of small or large patches of membrane, especially at the trigone and bas-fond, and by extravasations of blood into the submucous cellular tissue, caused probably by rupture of minute veins at the time of strong muscular contractions. In either event the mobility or pliability of the mucous membrane is lessened or destroyed by the inflammation which has reached its acme, and which now terminates in sloughing of the membrane (gangrene) perhaps to a very limited extent, or by an abscess opening through it into the bladder. It is also to be considered that the mucous membrane, rendered friable by previous inflammation, and thrown into irregular folds, may tear when it can no longer stretch under the powerful grasp of the hypertrophied muscular coat. This accident will occur the more readily on account of the anteverted position of the womb, which, I believe, always exists, and the pressure of which may explain the greater proneness to extensive ulceration of the female bladder, as averred by our morbid anatomists."

Treatment.—For my present purpose of study, I am led to regard all four of the inflammatory diseases of the urethra, bladder, ureters, and kidneys named as so many stages of the same pathological process. In short, if it were possible to cure the initial acute inflammatory lesions of the urethra and bladder, which rapidly become chronic, before the more internal organs are involved, the diseases of the ureters and pelves of the kidneys, thus arising from continuity of structure, might be almost, if not entirely, avoided. Hence the importance of recognizing early commencing urethrocele and cystitis, and treating them promptly, for, if neglected long, the upper urinary passages will surely suffer sooner or later in the order of sequences previously indicated.

Kolpo-cystotomy.—Kolpo-cystotomy, to secure physiological rest of the urethra and bladder, is undoubtedly the operation indicated for the relief of urethrocele coexisting with cystitis when the ordinary means at our disposal have failed; not dilatation of the urethra, nor an artificial opening between the canal and the vagina, expedients at best of questionable utility.

In the early stage of urethrocele, in which there is sacculation of the canal and retention of urine, I advocated on theoretical grounds, in the paper just quoted, the establishment of an opening into the canal from the vagina, a procedure which I called "tapping of the urethra;" but I soon saw that the practice recommended possessed no real merit, for the reason that the relief of the urethra afforded by such an expedient would confer little or no immunity upon the bladder against the extension of the inflammatory process to its cavity, and I therefore gave up the idea. Dr. T. A. Emmet proposed a similar operation on the urethra, several years later, which he called "button-holing of the urethra," but from what I have seen of the bad results of this procedure in cases which had been subjected to it by his followers, I would not be inclined to recommend it, for the reason that, when drainage from either the urethra or bladder or both is required, it should be established through an opening at a favorable point in the vesico-vaginal septum, where the opening afterward can be more easily closed, and injury of the functions of the urethra be entirely avoided. A large opening made here gives relief to both urethra and bladder by putting them in a state of physiological rest, and while they are being thus cured the ureters and pelves of the kidneys are guarded against further strain and the risk of commencing disease.

The practice of making a large opening into the bladder as a means of treating cystitis is itself of comparatively recent origin, but it is recognized generally by the profession as of great practical value. It has, however, been restricted in its employment, until recently, for the want of suitable artificial drainage of the bladder, by which alone the beneficial and legitimate results of the procedure can generally be obtained. I was the first in this country, as I believe, to treat successfully chronic cystitis by kolpo-cystotomy, which I did in my private hospital in New Orleans, in 1861. My first case was one of ulceration and concentric hypertrophy of the bladder coupled with urethrocele. The mucous coat of the bladder was thickened and redundant, and had a low grade of vitality. It was exposed to great tension from time to time on account of the violent and irregular contractions of the muscular coat. From its friable condition, no doubt, it readily became fissured and ulcerated, as was shown by the very minute disintegrated particles discharged through the urethra, which I recognized at the time with the unaided eye. The same pathology and mechanism of the walls of the bladder will serve to explain the occurrence of gangrene and perforation, not only of the mucous but of the muscular coat as well, in bad forms of recurrent cystitis, a case of which I could here cite if time permitted.

The very large opening, nearly the size of a silver dollar, which I finally made in the vesico-vaginal septum of my case referred to, afforded open and free vaginal drainage, and within one year all the diseased structures were completely cured by it, and the artificial fistula closed. The cause of failure to get the good effects of this procedure, in the hands of most surgeons who have employed it since, I am convinced, is because they do not make a sufficiently large opening.

To illustrate this point I will cite here a case—Mrs. S——, of Ohio, aged thirty-two, who recently came under my care—in which the initial stages of urethrocele and cystitis were completed after six years, with the development, as is believed, of ureteritis in the right side, in the regular order of sequences. The operation of kolpo-cystotomy was performed by one of the ablest gynecologists of New York, but, notwithstanding his acknowledged skill, the disease was only ameliorated for a time, resulting no doubt from the smallness of the opening he made and his want of a suitable form of artificial drainage. The patient, in spite of kolpo-cystotomy, after five years of further development of sequences (April 11, 1888) was admitted into my service in the Woman's Hospital, presenting all the terrible consequences of renewed and perpetuated sufferings, with blighted hopes and ceaseless dread of death from unknown causes. I found the fistula made for drainage five years before, situated a little to the right of the mesian line and very near the cervix uteri, a mere longitudinal slit through the thickened and contracted vesico-vaginal septum. It would about admit a No. 10 bougie, and through it protruded a small knuckle of the thickened vesical mucous membrane. The urethra had gone through all the stages of urethrocele, from an attack of urethritis occurring four days after marriage, and the bladder was in a state of concentric hypertrophy with a retaining capacity not exceeding three ounces of water. The patient says that she did not experience any real benefit from the operation she underwent until about six months afterward, when she got out of bed and began to walk about, attributed properly by her to a free escape of the urine, in obeyance, of course, of the law of gravity. The most of the symptoms in her right side from this time on continued to improve. But this amelioration of her sufferings was only of short duration. Pains soon began in the left groin and lumbar region, and they radiated down the thigh to the knee and foot, and came on in paroxysms not unlike those of renal colic. At the end of three years (two before admission into the hospital), though relieved almost entirely of her sufferings in the right side, the paroxysms of pain in the left had already become more frequent and severe in character, which were often followed by free discharges with the urine of thick and offensive pus. This condition of things continued to grow worse and worse until she entered the hospital. She had a bad form of retroflexion and fixation of the uterus. With all her varied sufferings of eleven years' standing, greatly aggravated no doubt from the last-named cause, I found her to all appearances in a state of robust health. But she was nervous and unable to sleep, results no doubt of the increased frequency and severity of the pains in her urethra, bladder, and left side, combined with the irritating effects of the constantly escaping ammoniacal urine. The treatment I proposed in the case was the correction of the displaced uterus and the successful establishment of intravaginal drainage, two most essential steps of treatment, I conceived, and without which I did not think it possible that any good could be accomplished.

Here the pathology and obstacles in the way of treatment were not unlike those usually found in certain forms of chronic cystitis in the male subject, resulting from old strictures of the urethra, and enlargements of the prostate gland. These two diseases, as is well known, bear a direct relation to dilatation of the ureters and surgical kidneys, which are usually rapid and certain in their developments; but they are no less constant and uniform in the production of their sequences than were found to exist in the case just cited, resulting from urethrocele and cystitis.[1]

From all this, therefore, it will be seen that I advocate and recommend for the successful treatment of urethrocele and chronic cystitis, alone or jointly, an opening in the vesico-vaginal septum between the orifices of the ureters, to secure physiological rest—the opening to be the size of a silver half-dollar to that, even, of a silver dollar, according to the advanced stage of the disease and the time it is desired to keep the structures at rest. This is to be coupled now, of course, with my system of intravaginal drainage, to protect the raw edges of the wound and the vaginal tract from the evil effects of the urine and to guard the patient against stillicidium. The main features of my procedure regarding the size of the artificial opening I have now clearly set forth; they are, I know, in contravention to the usually accepted practice.

---

[1] June 30th. Progress proved necessarily slow in my first efforts to restore the displaced uterus and establish satisfactory drainage, owing to the greater immobility of the organ, and consequently the greater angle to be overcome in the adjustment of my utero-vesical drainage support than I supposed in the outset of the treatment. Notwithstanding these obstacles, however, and the restiveness of the patient, the gradually increasing mobility of the uterus and the daily improved state of her health encouraged me to persevere. I believed it was only a question of a little time before I should begin to secure beneficial results from the plan pursued. Matters thus went on until I became further convinced that the old fistula, from the smallness of its size, and the partial closure of it nearly all the while by the teat-like protrusion of the vesical mucous membrane, were obstacles even more grave than those just mentioned. These obstacles, to my mind, accounted for the former persistency of the pains in the right side, and now the renal colic-like pains in the left. A more minute and careful examination at this juncture of the pathological anatomy of the vesico-vaginal septum, especially in the locality of the vesical orifice of the left ureter, fully confirmed my impressions upon these points. Here I found the area of the structure contracted down to one-fourth at least of its original dimensions. It was thickened in about the same proportion, hard, resisting, and exquisitely sensitive under pressure of the finger and depressor. From this further study of the parts, I now thought it possible that, from the incompleteness of the relief—after the operation of kolpo-cystotomy five years before—the hypertrophy of the muscular coat of the bladder had itself not only gone on increasing in the locality indicated, but that the original cystitis had been followed here by ulceration of its mucous coat as well, thus causing in this way abnormal relations of the parts, and mechanical obstruction to the outflow of urine from the corresponding ureteral orifice. I therefore decided to perform left kolpo-uretero-cystotomy, in order to give a direct outlet to the implicated ureters, which I did in the supported knee-elbow position, on April 27th, in the presence of several physicians and the house-staff of the hospital. I made as large an opening as the restricted limits of the diseased structures would permit, leaving a longitudinal strip of tissue between the old and new openings, the breadth of the index-finger. I found the thickness of the structures fully five-eighths of an inch, and an artery in the upper border of the opening that spouted blood almost equal to a divided radial. Only by the quick application of a long pair of compression-forceps was the patient saved from excessive loss of blood. The orifice of the imprisoned ureter could not now be discovered, nor could the morbid changes of the muscular and mucous coats of the bladder around the newly made opening be carefully examined, owing to the free oozing of the blood. Suffice it to say, that a few continuous catgut sutures in the border of the fistula at the bleeding points, and the application of a small pad moistened in a twenty per cent. solution of subsulphate of iron, controlled effectually the hemorrhage. In this way I put the patient in the best possible condition for renewed progress in treatment by utero-vesical drainage, combined with elevation and support of the uterus. As might have been expected from a fresh wound in the parts, there was for eight or ten days considerable increase in discomfort of the patient, arising mainly from flooding of the raw edges of the wound with alkaline urine. But, nevertheless, the cavity of the bladder under the new order of things soon began to enlarge, and the thickness of the vesico-vaginal septum to perceptibly diminish, thus showing that the mucous coat of the bladder had not undergone ulceration. It was not until June 3d, thirty-six days after the operation, could I find the affected ureteral orifice, and explore the tube up to the pelvis of the kidney. This I did first with a delicate probe for a few inches, and then with a French catheter No. 8. The result was the escape through the catheter of ten drachms of pus and urine, white, thick, and cloudy, from a point not exceeding one and a half inch up the ureter. The pelvis of the kidney and ureter were then irrigated with a solution of bichloride of mercury, 1–20,000. Again, June 5th, two ounces of a simiar fluid were drawn off from a point about the same height in the ureter, containing a large amount of pus and albumen with acid reaction, and specific gravity of 1.019. This exploration showed that when the eye of the catheter was carried into the pelvis of the kidney and irrigation commenced, it had to be withdrawn three inches from the kidney before the fluid would begin to run through it, thus proving that the sacculation was not in the pelvis, but low down in the ureter. Still again, on June 8th, with the same precautions of introducing and withdrawing the catheter through to the dilated portion of the ureter, three ounces of fluid of the same character were taken away, and irrigation made. The fluid drawn off this time was acid, contained pus, epithelia, and some albumen, but no casts or crystals. The catheter, now left in the ureter five hours, showed that the secreting capacity of the left kidney was equal to, if not greater than, that of the right. The temperature next day, accompanied by nausea and vomiting, rose to 103.5° F., but it gradually came down, and the irrigation was resumed, though at longer intervals. The improvement of the parts was slow but progressive to the date of this note, when the patient left the hospital to return home to recuperate her strength for future treatment, when the hospital opens in the autumn.

Thus have I diagnosticated in this case sacculation of the left ureter, with obstruction just above the orifice to the outflow of the retained secretions, without perceptible disease of a serious nature in the corresponding kidney, resulting from concentric hypertrophy of the muscular coat of the bladder, and constriction within its grasp, probably, of the corresponding portion of the affected ureter.

Whatever may be the final result of the treatment in the case, now cut short for three months, I can at least claim thus far that a correct diagnosis of sacculation of the affected ureter has been reached, and that the domain of gynecology in this direction has been extended. It remains yet to be seen what the exact limit of such work in this new

Ureteritis and Pyelitis.—I have referred particularly in the preceding remarks to the teachings of my first operation of kolpo-cystotomy, in 1861, and the result of it, together with the case precited, because they have a direct bearing upon ureteritis and pyelitis, belonging to the third and fourth classes of our division. They show the tenor of the line of work that I have pursued during all the succeeding years of my experience, which has finally led me to diagnosticate, differentiate, and treat successfully the diseases named. This has been done by a careful study of certain groups of symptoms and physical signs characterizing these and other lesions sketched in the first part of this paper. I will here briefly point out the more important differences between ureteritis and pyelitis, from a practical point of view. Ureteritis indicates its presence by congestion and thickening of the mucous lining of the vesical portion of the ureter, and by diminution of its lumen, coupled with intense morbid sensibility. Pyelitis evinces a thickening or hypertrophy of the walls of the ureter in some part or the whole of its extent, with partial or complete dilatation, coupled with no greater sensibility than usually accompanies the lodgment of a similar sized instrument in the male urethra for the relief of a stricture.

I am sorry that time does not permit me to report all of my cases, in order to illustrate and substantiate more fully what I have said. Each presents certain points of interest, but at the same time there is a uniformity in the principal features of all. The case of Mrs. B——, already related in the journal cited, I regard as typical of my fourth class, where dilatation of the ureter had occurred and the inflammation had extended to the pelvis of the kidney.

Kolpo-uretero-cystotomy.—By kolpo-uretero-cystotomy, described in my paper on the treatment of chronic pyelitis, and now advocated and recommended for the successful treatment of renal tenesmus, I mean the making of an opening through the vesico-vaginal septum not smaller than a silver half-dollar, and having specific and close relation to the outlet of the affected ureter and kidney. When of this size and in this situation, it insures a direct escape of the secretions from both organs into my intravaginal drain, from which a state of the most complete physiological rest is obtained, with the best possible aseptic surroundings of the newly-made wound. In this way the greatest comfort is conferred upon the patient in any position she may choose to take for sleeping, sitting, or walking.

While it may seem to some, with no experience in such matters, that my recommendations for the establishment of the large openings in the two procedures outlined shows a needless sacrifice of tissue, with which I have indeed been charged by writers with regard to the first, yet, nevertheless, I am prepared to maintain the correctness of the practice on the basis of the good results I have obtained by them, and from having seen very defective open drainage and the evil consequences therefrom, when even larger fistulous openings existed than I have advocated, resulting from parturition. It is well to bear in mind that I operate either in the supported knee-elbow or left lateral position, using my bilateral dilating speculum, which spreads out the septum, very elastic in character, and the opening when made in it in this state of tension naturally seems large. From these circumstances it may be readily inferred that the loss of tissue is always more apparent than real.

Renal Tenesmus.—This brings us now to the study of renal tenesmus as a result of chronic inflammation of the mucous membrane of the vesical portion of the ureters, the main object of this paper. By renal tenesmus I mean violent and painful contractions of one or the other ureter and corresponding pelvis of the kidney, with marked tenderness or soreness under pressure of the latter organ, proceeding from morbid irritability of both structures. The pains occur in paroxysms, which vary in frequency, duration, and severity in different cases according to the stage of the preceding ureteritis and the extension of the lesion to one or both sides. As a rule, it is confined at first to the groin on one side of the body, and afterward to the corresponding lumbar region. In the more severe attacks the pain, besides being violent in these situations, radiates to the hip, the outer and inner sides of the thigh, the knee, leg, and even to the toes. Cramps of the muscles of the lower extremity on the affected side also occur in these severe paroxysms. In the well-marked cases, attacks of this sort come on daily, or even several times a day. They are most frequent and severe during the menstrual periods. The patients describe them as occurring most often during the night. They awake with a pressing desire to urinate; the emptying of the bladder is accompanied by more or less pain and spasm, and its evacuation is followed by a cramp-like pain ascending along the course of the ureter to the kidney, and radiating to the lower extremity. The patients sleep, as a rule, on the affected side, with the face turned toward the pillow, and it is the habit of many to draw the opposite thigh up over its fellow against the abdomen. The pain is excited in the early stages by the marital relation, which in nearly all cases becomes intolerable in the advanced stages of the disease.

Other symptoms are associated with the renal pain and the disturbance of the functions of the bladder. Anorexia, nausea, and vomiting are almost always present, especially during the menstrual periods, and as the attacks of vomiting are generally long continued, the vomited matters become stained with bile. Jaundice even is not an uncommon result. Hysterical symptoms form a marked feature of most of the cases. The patients start at the slightest noise, become despondent, cry, and laugh without sufficient cause, and sometimes have well-marked hysterical convulsions followed by a period of unconsciousness. Finally, in the advanced stages of the disease, after years of almost ceaseless pain, when dyspepsia, loss of appetite, nausea and vomiting, torpidity of the liver, constipation of the bowels, and yellowish tinge of the complexion shall have supervened, the general aspect of the subject is that of inanition or starvation, from which, with continually increasing physical and mental sufferings, death puts an end to the roll.

That the pains which I have described as constituting renal tenesmus are referable to ureteritis, beginning in the lower part of the ureter as an extension of cystitis, and are due to spasm of the affected ureter and pelvis of the kidney, appears not only from their situation and character, but also from the following physiological signs and observations.

Tenderness over the kidney on the affected side is usually present. Frequently I find a small area of great sensibility midway between the crest of the ilium and the last rib. There may also be tenderness on pressure in the groin. More important and characteristic than either of these signs is great tenderness at the ureteral orifice, and along that portion of the ureter which lies in the vesico-vaginal septum. The slightest pressure upon this part of the anterior vaginal wall on the affected side causes pain, which frequently ascends along the ureter to the groin and kidney. This, together with the sensitiveness of the urethra and the bladder, furnishes an explanation of the dyspareunia which is so commonly present in these cases. Pressure with even a few pledgets of dry cotton also gives rise to pain in the ureter. Looking back over my experience, I recognize these patients as those who were unable

---

field of investigation may be, and how much further general surgery can be depended upon for the relief of such sufferings by the sacrifice of an endangered or diseased kidney, approached from the opposite direction through the resources of lumbo-nephrectomy.

One is here naturally led to ask, of what value or practical use would attempted catheterization of the ureter for diagnostic purposes have been in such a case, made through the urethra with dilatation, or, as to that matter, "free handed" without dilatation, for which it has been claimed that dexterity and supreme skill are all-sufficient? For my part I answer that it took me thirty-six days to find the ureteral orifice, and I had the advantage, too, of a window in the vesico-vaginal septum through which I could examine and study well the inside of the bladder. I possessed in the procedure also a ready method for treating the existing inflammatory lesion in the ureter, besides being able to guard against acute attacks of cystitis.

to tolerate columning the vagina with dry cotton for displacements of the uterus and ovaries—a practice which I have pursued nearly twenty years.

Paroxysms of renal tenesmus may also be excited in a most striking manner by moderately distending the bladder with warm water. The pressure of the water, when sometimes only a few ounces are used, causes an irresistible desire to urinate, which, if not promptly relieved, is followed by the pain along the ureter and in the kidney, even in the corresponding hip and lower extremity down to the ends of the toes. The patients recognize the pain produced in this way as the symptoms which have been their chief source of suffering. The attacks of renal tenesmus brought on by either of these procedures may last for several hours or days, and are frequently accompanied by great mental excitement and hysterical manifestations. Hence the necessity of caution in adapting these means to the peculiarities of the case.

Corresponding to these clinical facts after a kolpo-uretero-cystotomy is done, we find great sensitiveness and irritability of the bladder and ureter. In the report of my first two cases of pyelitis, I stated that catheterization of the ureter caused but little pain. This is true in a normal ureter, and in some cases of pyelitis with considerable dilatation of the duct; but when pronounced ureteritis exists at or near the vesical orifice of the tube and renal tenesmus is present, the passage of the smallest instrument gives rise to violent paroxysms of pain. In the normal pelvis distention with fluid occasions moderate pain, identical in character with that we are considering, and the quantity of fluid thus injected becomes a measure of its capacity. When renal tenesmus is present, however, the pelvis of the kidney is intolerant of fluid, and the pain beginning before distention is reached may continue for hours. In these cases, therefore, the quantity of water that can be injected is rather a measure of the irritability of the pelvis than of its capacity.

This view of the causation and pathology of renal tenesmus is further strengthened by the results of treatment. As soon as the proper opening is made at the affected orifice of the tube, and the bladder and upper urinary passages are put at rest, coupled with suitable drainage and support of the uterus, the paroxysms become less frequent and soon disappear altogether.

Differentiation from Renal Colic.—The pain of renal colic also depends upon violent contractions of the muscular fibres of the ureter and pelvis of the kidney, and when renal tenesmus is severe there is a close similarity between its paroxysms and those of renal colic. The situation and character of the pains are identical in both, and associated with either there may be a frequent desire to urinate, cramps in the lower extremities, and nausea and vomiting. Both are due to spasm of the muscular fibres of the ureter and pelvis of the kidney; the distinction between them lies in the cause of the contractions. The contractions in renal colic arise from the impaction of a foreign body, usually a calculus in the ureter, causing the urine to collect in and distend the pelvis of the kidney above the seat of obstruction; the contractions which follow are a response to this powerful source of irritation, and the condition of the mucous membrane, whether healthy or diseased, has little to do with their occurrence. In renal tenesmus, however, the irritable condition of the lining membrane, the result of ureteritis, leads to violent contractions of the muscular fibres of the ureter and pelvis from much slighter causes, as, for example, increased tension of the urine during forcible expulsive efforts of the bladder, or, as happens in the bladder, the presence of the urine itself, especially if abnormal, may excite spasmodic contractions. Dependent upon the difference in causation of renal tenesmus and renal colic, each possesses certain distinctive features. An attack of renal colic continues, as a rule, with only short intermissions, until the calculus escapes into the bladder, and the concretion is afterward generally discovered in the urine; the paroxysms also recur at irregular and usually long intervals. The pain of renal tenesmus is less severe and long continued; it comes on more frequently, and the paroxysms, as we have seen, occur several times a day, and often from the most trivial causes. The most important diagnostic feature of renal tenesmus, however, is the facility with which an attack can be excited. When any doubt of the causation of the pain exists, it may be set at rest by making pressure over the ureter where it lies in the vesico-vaginal septum, or by injecting the bladder with warm water in the manner already described. The distinction, thus easily made, is all the more important, because an error in diagnosis, as I have known to occur, may lead the surgeon to perform lumbar nephrotomy and find no stone in the pelvis of the kidney.

Differentiation from Pains in the Ovaries and Tubes.—In the milder cases of renal tenesmus, where the pain is referred to the ureter in one or the other iliac region and radiates less frequently to the pelvis of the kidney, the pain may be ascribed to ovarian neuralgia or disease of the ovary and Fallopian tube. This error is all the more likely to occur because at times there is no pus in the urine, and hysterical symptoms commonly referred to ovarian irritation may be highly developed; the patient may also describe the pain vaguely as being in the side, as often happens, and her sufferings may be intensified during the menstrual periods. That this error in diagnosis is not a mere theoretical possibility will be seen by the histories of two cases which I will presently report. In one of them the ovaries and tubes were removed a year ago by a distinguished laparotomist of New York; in the second case a Tait's operation was urgently recommended by another. In order to ascertain the cause of the pain the urine should be frequently examined, especially at or about the menstrual periods, the condition of the bladder should be inquired into, and the situation and character of the pain carefully noted; if then any doubt remains, pressure over the ureter should be tried and the bladder injected with water. The excitation by these means of an attack of renal tenesmus, which the patient recognizes as being identical with the pain she has suffered so long, will at once clear up the diagnosis. May not a more careful and painstaking study of the differentiation between deep pelvic pains, regarded usually as significant of diseases of the ovaries and tubes on the one hand, and the group of symptoms characterizing renal tenesmus on the other, serve to explain the too frequent resort to oöphorectomy as is now believed to be the case by the majority of the profession?

Treatment.—In order to present a clinical picture of our third class of cases, where the inflammation is confined to the bladder and ureter, and is associated with renal tenesmus, I will relate to you the histories of the following cases, together with their treatment:

Case I.—Mrs. G——, aged twenty-six, a laundress, was admitted into my service in the Woman's Hospital, November 30, 1887. Her symptoms began during her second pregnancy, seven years ago, with pain in the left groin which afterward extended to the corresponding lumbar region. Micturition also became frequent, and she noticed a strong odor and thick deposit in her urine. In 1885, she was under my care for seven weeks. At that time there existed a marked retroversion of the uterus and her urine contained pus. She was treated for the displacement by columning the vagina in the supported knee-elbow position, with ordinary dry cotton; but was unable to tolerate the required pressure, and left the hospital without having received any benefit. She was also under treatment for nearly two years in the out-door department of the hospital, but did not improve. In the spring of 1887, both of her ovaries and tubes were removed by a laparotomist of New York City. She entirely recovered from the operation, and during the past year has only menstruated twice. Her sufferings were not relieved, but rather increased, by this operation, especially those relating to the bladder and head.

When she was admitted into the hospital in November last, she had then been suffering from great vesical irrita bility for seven years. For five years she had been obliged to get up to empty her bladder many times during the night, and during the exacerbations of her symptoms, which occurred at the menstrual periods, she was unable to hold her urine longer than half an hour. The evacuation of the bladder was usually effected by violent and painful contractions or cramps. After the small amount of urine which she could retain was expelled, pain would ascend from the bladder into the left groin and continue for a few minutes or half an hour. At first the pain was confined to the left iliac region, running upward from the inguinal ring along a line to the lumbar region. At a later period, when her symptoms had increased in severity, it extended to the groin and lumbar region on the opposite side, and finally to the corresponding hip and down the thigh to the knee. Violent and long-continued cramps of the muscles of the lower extremities frequently occurred during the paroxysms of pain. The position in bed which she found the most comfortable was on the right side. (In this respect the case is exceptional; most of the patients lie on the affected side.) Her appetite was poor, and during the menstrual period she suffered most from nausea and vomiting.

On palpation, a point was found in the left lumbar region where moderate pressure caused the patient to cry out with pain. Vaginal examination disclosed great tenderness at the vesical extremity of the ureter. The uterus was now retroflexed instead of retroverted as previously existed, inclined to the left side of the pelvis, and immovable. A mass of exudation could be felt in the posterior cul-de-sac, all legitimate results of the operation she had previously undergone for removal of the ovaries and tubes. The urine contained a small amount of pus; otherwise, was normal.

On December 9th I made an opening in the bladder immediately in front of the orifice of the left ureter. The night after the operation the patient slept soundly, the first time, she declared, in two years. About ten days after the operation the ureter was searched for and found with some difficulty on account of the great tenderness of the bladder at this part. Catheterization and irrigation of the ureter and pelvis of the kidney were painful. The injection of only a drachm of water through the catheter caused violent paroxysms of pain, radiating down the corresponding hip, thigh, and leg. Owing to the extreme pain arising from the passage of the catheter, and my failure to find any pus in the pelvis of the kidney, I gave up the practice after a few trials, not deeming it justifiable under the circumstances.

While the patient remained in the hospital her symptoms steadily improved, the paroxysms of renal pain becoming less and less frequent. Owing to the fixation of the uterus, the use of the drainage instrument was less satisfactory in this case than in any I have treated. My utero-vesical drainage support collected the urine fairly well, but, owing to the pain which it occasioned by pressing up the uterus, it could not be worn. A special instrument, made short so as to occupy the vagina in front of the uterus, was tried. This did not cause pain, but collected only a part of the urine. After the patient, however, got accustomed to the presence of the instrument and learned how to manage it better, very good drainage was secured.

The patient left the hospital after having been under treatment about four weeks. I saw her a few days ago. She was relieved of all her symptoms. She says she is able to do the hard work of a laundress all day, and sleeps soundly at night. When asked if she would prefer to go all her life with incontinence of urine rather than return to her former condition, she answered, "A thousand times."

In the above case the vesical and renal symptoms were well marked, but the hysterical phenomena which, as a rule, form a prominent feature of these cases were absent. In the following case they were well developed.

CASE II.—Mrs. M——, aged twenty-six, was married at sixteen, and has given birth to three children. Soon after marriage she began to suffer from pain in the urethra, and a frequent desire to urinate following sexual intercourse, and at this time she first noticed a thick deposit in her urine. During her first pregnancy, nine years ago, these symptoms became worse, and in the latter months she began to have pain in the right groin radiating to the region of the kidney. These symptoms continued and were aggravated during her subsequent pregnancies. During the early months of her second pregnancy her urine contained blood. For a long time she complained of pain in the head, and suffered from nausea and vomiting during her menstrual periods, at which times all her symptoms were aggravated. In consequence of her sufferings she became nervous and hysterical. Frequently, at the end of a paroxysm of pain in the ureter and kidney, she would have convulsive movements ending in unconsciousness which continued for half an hour or more. For the relief of the pain she became habituated to the use of morphine and chloral, and took large doses of these drugs. About two years ago an abscess formed in the right iliac region. It opened into the rectum, and the discharge continued for about three months, when it ceased. She recovered from all the symptoms referable to the abscess except a dull, aching pain in the pelvis.

The patient was brought to me from Texas by her family physician, for the purpose of having her ovaries removed. His opinion as to the advisability of the operation had also been strengthened by that of a laparotomist of New York, who diagnosed a pyosalpinx. I first saw her on March 15th.

On palpation, a point of tenderness was discovered in the lumbar region over the kidney. Examination of the pelvis in the supported knee-elbow position disclosed the following: The urethra was much thickened, feeling like a hard rounded cord beneath the finger, and the vesico-vaginal septum also seemed indurated and resisting. The uterus was prolapsed and inclined toward the right side. A corresponding displacement of the right ovary existed; it was drawn to the right and imprisoned beneath the uterus. Pressure with the finger on the anterior wall of the vagina, over the line corresponding to the course of the right ureter, caused severe pain which radiated along the ureter to the kidney and downward to the hip, thigh, knee, leg, and even to the toes. Pressure over the left ureter occasioned little inconvenience. On examining the urine, it was found to contain a moderate quantity of pus.

A few days after the first examination, in order to support the uterus and ovaries and to gradually free them from their confined position, I commenced columning the vagina with dry cotton in the supported knee-elbow position. I introduced a few pledgets of ordinary cotton, employing very gentle pressure, as is my custom at first in cases where the parts are sensitive. After a few trials this plan of treatment had to be abandoned. The presence of the cotton caused the same group of symptoms which were excited by pressure over the ureter with the fingers.

An attempt was next made to wash out the bladder. When I had injected about three ounces of warm water through a small, soft catheter introduced into the bladder, the patient began to complain of pain. The pain soon became very violent, extending, as usual, along the ureter to the kidney on the right side, and down the thigh to the toes. The paroxysm lasted two or three hours, ending in a hysterical attack followed by a period of unconsciousness.

Failing to benefit my patient by other means, on March 31st I performed right kolpo-uretero-cystotomy. I was assisted by Dr. J. F. Chauveau, of New York, Dr. Joseph Letcher, of Texas, and my son, Dr. Nathan G. Bozeman, who had charge of the patient after the operation. I made an opening in the bladder about the size of a silver half-dollar, immediately in front of the orifice of the right ureter. The vesical wall was found much thickened and the cavity of the bladder contracted. A utero-vesical drainage support was introduced into the vagina; it collects the urine, and by its use the patient is kept almost perfectly dry.

Since the operation, there has been a marked improvement in the patient's condition. She is now entirely free from the attacks of renal pain, is able to sleep all night, and has left off the use of opium and chloral. She can sleep on her left side, which she has not been able to do for two years. Her appetite and general condition have improved, and she is able to go out of doors and take exercise. Nausea and vomiting, which had hitherto been constantly present during menstruation, were absent at her last period, and the exacerbation of her symptoms, usual at this time, did not occur. Owing to the elevation of the uterus and ovaries by the drainage support, even the symptoms referable to these organs have almost disappeared. In short, now, five weeks after the operation, the patient declares she is entirely relieved and wants to return home. She has increased five pounds in weight since the operation. In this case, owing to the marked and rapid improvement in all the symptoms, I decided not to catheterize the affected ureter and kidney, believing this to be unnecessary. The drainage was almost perfect from the beginning.[1]

In order to secure the best results in the treatment of diseases of the bladder and upper urinary passages by the operation of kolpo-uretero-cystotomy, the bladder must be kept free from urine. My practice, as previously stated, is to make the opening about the size of a silver half-dollar. My experience has taught me that an opening in the vesico-vaginal septum of this diameter will contract to the size of the index-finger, depending, of course, upon the degree of hypertrophy the structure has undergone.

But this is not all that is necessary to secure free open drainage and physiological rest of the bladder. The posterior wall of the vagina lies in contact with the fistula and tends to obturate the opening. In the recumbent posture, also, the orifice of the vagina is on a plane about an inch and a quarter higher than the most dependent part of the posterior cul-de-sac. The urine must therefore first partly fill the vagina and bladder before it can escape from the body. Furthermore, in unmarried women especially, where the perineum is intact, a small ostium vaginæ prevents free egress of the urine. Another cause of retention in cases of fistula was first pointed out by Jobert de Lamballe; to wit, extreme anteversion of the uterus. Here the fundus being displaced forward, it carries the superior wall of the bladder before it, while at the same time the vesico-uterine junction is drawn backward by the cervix. In this way is produced a fold in the bladder, and if the fistula be situated high up, it is more or less completely occluded. From some of these causes, it is a matter of common observation that patients suffering from fistula are frequently able in the recumbent posture to retain almost all the urine in the bladder and vagina—as in a common cavity, so to speak. It is evident, when great irritability of the bladder is present and the urine is not entirely drained off, spasms of the organ will persist, the tendency to reflux of the urine into the ureters will continue, and the group of renal symptoms and complications which I have described will not be relieved. The case of Mrs. S——, referred to in a previous part of this paper, proves this point in a striking manner. Here kolpo-cystotomy, it will be remembered, had been performed for cystitis five years before. But little benefit was derived from the operation, distress about the bladder continued, and ureteral and renal complications in the left side developed two or three years afterward. As evidences of the persistence of the spasms and excessive action of the bladder, I found the walls of the latter, five years after the operation, hard, resisting, excessively sensitive under pressure, and about five-eighths of an inch in thickness, with a cavity of scarcely three ounces retaining capacity.

Another and more obvious advantage which follows the use of the drainage instrument is the relief of the discomfort and evil effects of incontinence of urine. It increases the scope of the operation, because without it I would hesitate to open the bladder in all but the graver cases of vesical and renal disease. By its use the patients are made comfortable; they complain of but little inconvenience, and wait with patience until the opening can be closed.

I have made some changes in the drainage instruments since I described them,[1] the most important of which adapts them for drainage when the patient lies on her side. Drainage is now secured in all positions of the body. At a future opportunity I will give an account of these improvements, and also a modification of the instrument which adapts it to treatment of incontinence of urine in young girls, arising from weakness of the neck of the bladder, together with other practical points resulting from a more thorough study of the subject.

Frequently associated with disease of the bladder and upper urinary passages there are, as we have seen, displacements of the uterus and ovaries. The uterus is generally inclined backward and to one or the other side of the pelvis. The distortion of the bladder near one of the ureteral orifices resulting from the uterine displacement, and in some cases the pressure of the fundus uteri upon the inflamed ureter, tend to keep up the cystitis and to aggravate the ureteral pain. It is therefore important that the uterus and ovaries should be restored to their normal positions. Before the bladder is opened, owing to the tenderness of the urethra and the extreme sensitiveness of the ureter on the affected side, the use of a uterine support or pessary, however soft, is impossible, and in most instances even gentle pressure with a few pledgets of dry cotton cannot be borne. Fortunately, after the opening is made the uterus tends to be pushed forward by the pressure of the abdominal viscera, in order to fill the space formerly occupied by the bladder, and, owing to the rapidly diminishing tenderness of the ureter, the vagina soon becomes more tolerant of pressure.

In order, therefore, to secure the advantages of elevation and support of the uterus and ovaries in combination with drainage of the bladder, the drainage instrument is made thick and rounded at its upper extremity, where it lies in the posterior cul-de-sac beneath the cervix uteri. As a uterine support, its mode of action is similar to that of the dry-cotton column applied in the manner I use it. The instrument lifts up the body of the uterus, stretches the posterior wall of the vagina, and tends to carry the cervix backward. Not resting against the symphysis pubis as does a Hodge pessary, but conforming to the axis of the lower part of the vagina, and sustained chiefly by the perineum and vaginal walls, it exerts an elastic pressure upon the uterus. The instrument consequently yields during sudden movements of the organ, following jars of the body or expulsive efforts of the abdominal muscles. The mucous membrane of the anterior wall of the vagina is applied closely to the concave upper surface of the drainage support, and sinks into the perforations made in it for the passage of the urine. This gives steadiness to the instrument and increases its efficiency as a uterine support. At first the drain sometimes causes discomfort; immediately after the operation it is necessary to use a very small instrument, and exceptionally, as in the case of Mrs. G——, the form of the drain must be modified.

---

[1] The patient continued to improve until May 28th, fifty-eight days after the operation, when she left New York for her home in Texas, having up to this date gained sixteen pounds in weight. The following is an extract from a letter to me after her four days' travel in the cars:

"Lampasas, Tex., June 8, 1888. . . . Was sick the first day, but after that got along very well. Did not sit up at all. Had my berth down all the way. Found my family quite well, and delighted to see me looking so well. Have felt real strong since I rested from travelling. Have not felt so well for years. Suffer very little pain anywhere. My friends all think it wonderful that I should have improved so much in so short a time. The instrument is working very well, but the drainage is not perfect, some water seeming to stay in the instrument. . . . I can walk now and sit down with perfect ease; can hardly tell I have the instrument on."

I have since performed three more operations for renal tenesmus, now making six in all, with results equally satisfactory, if not more so, than in the two cases here reported.

[1] American Journal of the Medical Sciences, March and April, 1888, and Transactions of the Ninth International Medical Congress, 1887.

I have found continuous irrigation and drainage to be of great value just after the operation, and my system of intravaginal drainage has been extended to accomplish this. For the perfection of the system in the application of suction I am indebted to my son, Dr. Nathan G. Bozeman, and Dr. William B. Gilmer, who have recently been deeply interested with me in working up the subject of drainage, and have materially contributed to my success by their experimental work. This system of continuous irrigation and drainage is of great practical importance and has a wide range of usefulness in general surgery, but the further consideration of it, together with the several improvements made in my drainage supports, will be the basis of a future paper.

In my paper on pyelitis, so frequently referred to, I explained sufficiently the method of irrigating the kidney. In cases where cystitis and ureteritis associated with renal lesions are present, the indications for the employment of this procedure are not so clear as when the inflammation has extended to the pelvis of the kidney. My experience so far tends to show that physiological rest and drainage of the bladder and ureter are all that are necessary when only these organs are involved. After the extreme sensitiveness of the parts has subsided, however, the passage of the catheter may be found useful for its tonic effect, as is the case in a similar condition of the mucous membrane of the male urethra; but further experience is needed to settle this point.

Now, a few words about the time which should be allowed to elapse before closing an artificial fistula. All thickening of the vesical walls and tenderness about the urethra, bladder, and ureter must have disappeared. From six to twelve months, as a rule, are required to accomplish these results. Of late I have adopted a useful method of determining this point experimentally. I introduce a large cylinder of hard rubber—one of my intravaginal dilators—which obturates the fistulous opening and keeps the urine in the bladder. If the patient can wear this instrument for a week or two without the occurrence of any distress in the bladder, the opening may be closed at once and the bladder allowed to take on its normal functions.

A LETTER OF DR. DANIEL DRAKE, written forty years ago, was read at the recent meeting of the Indiana State Medical Society. It gives an idea of the condition of Western State Medical Societies at that time.

"CINCINNATI, O., May 22, 1847.

"I returned yesterday from the annual meeting of the medical convention of Ohio at Columbus. Of the great utility of such conventions to those who compose them, if for no others, there can be no doubt; and that when the time shall come that they are numerously attended by the physicians of every State in the Union, the profession in the United States will be found advancing in aspiration and in intelligence much beyond anything we have yet seen. One hundred and twenty physicians of thirty counties of this State were present. The fifth pair of nerves were exercised not less than the seventh, and the discussion of the latter did not send forth a single angry or resentful expression. There was emulation without rivalry and wit without wine. DAN DRAKE."

THE JUICE OF CINERARIA MARITIMA IN CATARACT.—The juice of cineraria, a plant growing in Trinidad, is said by a Spanish practitioner, Dr. Mercer, to have a remarkable curative power in cataract. Dr. Mercer was himself the patient, and testifies to its remedial power in his own case.

A CASE OF ARSENICAL PARALYSIS, WITH SYMPTOMS OF LOCOMOTOR ATAXIA.[1]

By FREDERICK PETERSON, M.D.,

NEW YORK.

THE following case of arsenical paralysis,[2] with unusual symptoms of locomotor ataxia, is of interest:

E. A. D——, female, forty-two years of age, admitted February 15, 1887. A week or ten days after a second marriage in November, 1886, she became acutely melancholic and made several attempts at suicide. Father and sister insane. A week after the onset of melancholia the patient took a tablespoonful of "Rough on Rats," which is a mixture of arsenious acid and starch paste. Vomited two or three hours afterward, the vomiting continuing the first night and following day. In a day or two she had hemorrhages from the bowels. Paresis of all four extremities was manifested in two or three days, and gradually grew worse. For weeks afterward she complained of "crampy pains" in feet, calves of legs, hands, and abdomen. On admission these pains were still severe, and she had no use of arms or legs. There was great muscular atrophy, marked arsenical tremor, no patellar reflex, no anæsthesia or analgesia, but a slight hyperæsthesia.

February 17th.—Hands and feet feel numb and have a prickling sensation in them. Has had itching feeling over body and limbs, formication in feet, and the sensation of a cord drawn tightly round her waist. "Throat felt as if gone at times" (anæsthesia). At present in bed. Legs are flexed and somewhat contracted, extension causing great pain in flexor muscles and tendons. No tenderness over spine at any point. Muscæ volitantes often. Drop wrists and ankles. Faradic reactions of nerves and muscles of limbs lost. A general treatment was begun with iodide of potash, massage, and electricity, which was continued throughout the case.

February 25th.—Subject about once daily to a fainting spell lasting some fifteen minutes, with dyspnœa. Cardiac sounds feebler than normal.

March 6th.—Feet slightly œdematous. Urine examined now and at other times for sugar and albumen, with negative result.

March 19th.—Begins to move fingers and feet somewhat better.

March 25th.—Able to feed herself and is trying to knit. Pains in extremities still great at times.

April 19th.—Gradual but very slow increase of motor power. Gaining in flesh. Feet much swollen.

May 17th.—Walks a short distance alone.

July 16th.—Sews, knits, writes letters, but fingers still straighter than normal, and tremor still very marked. Cannot flex fingers into palms with ease or force. Still no patellar reflex.

August 30th.—Walks without assistance any ordinary distance. Motor power still increasing gradually. Tabetic gait.

September 26th.—In bed several days; weak, feverish, great increase of muscular tremor, vertigo, accelerated pulse, nausea, anorexia (a crisis?).

November 15th.—Still suffering from effects of relapse. Up only afternoons. Cannot walk as well as formerly, but gaining.

December 2d.—Walks now as well as at any time since residence in the hospital, and seems quite strong.

January 7th, 1888.—Has tabetic gait and entire absence of the tendon reflexes (the break in the reflex is on the sensory side). Use of arms also imperfect. Legs slightly œdematous.

January 21st.—Physical condition improved.

February 16th.—Œdema of lower extremities has disappeared.

---

[1] Read before the Neurological Section of the New York Academy of Medicine, May, 1888.

[2] This case will be reported in full detail, with the mental history also, in the next number of the American Journal of Insanity, by Dr. Charles E. Atwood, of the Utica Asylum.

March 11th.—Able to walk a little more steadily.

March 13th and 14th.—Attack of acute indigestion; diarrhœa, nausea, and colic.

March 26th.—Has apparently passed through one of the gastric crises of locomotor ataxia with an unusual amount of tremor, which is still present when she sits up.

April 17th.—Discharged. Patient lost her hair to a considerable extent, and was cachectic. There are some points of difference between this case and those of Seligmüller and Dana. The occurrence of two apparent gastric crises is particularly noteworthy. There is no reason, in my opinion, why arsenic should not attack the spinal cord as well as the peripheral nerves and produce a condition very much like true locomotor ataxia.

ACUTE PEMPHIGUS—DEATH.

By T. HAMILTON BURCH, M.D.,

NEW YORK.

The following case is reported on account of its rarity. If a fatal termination had been anticipated a photograph of the eruption would have been obtained, as it was very characteristic and perfect. Patient, I. T——, aged nineteen, colored; occupation, ship-steward. History of chancre (syphilis?) five years ago. Never had an eruption, no alopecia, or rheumatism. He was told at a dispensary that the sore was syphilitic. In appearance he was healthy, well nourished, and robust; weight, one hundred and eight pounds; height, five feet ten inches. He contracted small-pox in April, 1888, on board ship, and was removed to the small-pox hospital on Blackwell's Island, whence he was discharged cured, May 12, 1888. The following day an eruption of a number of small distinct, circular patches appeared on the scalp, covered with a bleb, and spread rapidly, the intervening skin being healthy. Symptoms complained of were some pruritus, headache, nausea, constipation, and general nervousness. The size of these bullæ varied, and as the eruption appeared on the neck, some of the blebs were not larger than a half-dime; others were the size of a silver dollar. In the course of a few hours the centre of each patch became elevated, and an opalescent bleb formed surrounded by an erythematous ring. The contents of most of them became so great that rupture occurred; but the smaller ones shrivelled up and were succeeded by thin, brownish-colored crusts. As the eruption extended to the breasts, the bullæ on the scalp commenced to dry. In forty-eight hours the entire body was covered, including the soles of feet and palms of hands. The duration of the illness was fourteen days. The temperature throughout was normal, respirations twenty to the minute, pulse one hundred and ten and of good volume. The patient was always pleasant and rational when seen by the physician, but the nurse reported that on the third day of his illness he had an attack of acute mania, and insisted on dressing and reporting to his ship for work, but on attempting to leave his bed he was seized with an epileptic fit and remained in that condition for about three minutes. Several of these seizures occurred, but the attending physician, whose calls were frequent, never saw him in any condition but one of perfect consciousness and good nature, and standing his sickness with manly fortitude. The stomach and bowels responded to treatment, and when the patient followed the prescribed diet he had no difficulty in digestion. I was hurriedly summoned on the morning of the fourteenth day, as the patient was thought to be dying. On reaching his bedside I found him quiet and conscious. The nurse stated that "he had just come out of a fit." His condition was excellent, and there was no indication of heart-failure, of collapse, or of pulmonary œdema. Five hours afterward I was again hurriedly called, and on my arrival found the patient dead. Not knowing any cause for death, and anxious to ascertain the condition of the brain, I obtained consent to an autopsy. Twelve hours after death, with the aid of Dr. R. W. Amidon, a post-mortem examination was made. Brain carefully examined and found perfectly normal. Chest revealed old extensive and very firm pleuritic adhesions. Lungs slightly œdematous. Heart normal, containing some blood-clots, but evidently of post-mortem origin. Kidneys: The cortex was very small, and there was apparently slight parenchymatous nephritis. The urine had been examined repeatedly before death, but no casts were found, and only a very faint lime of albumin by Heller's test. The urine taken from bladder after death was carefully examined by Dr. Amidon for casts, but the microscope revealed nothing abnormal. The treatment throughout was symptomatic. For the eruption, mild, protective, and soothing lotions acted the best. His mother stated (after death) "that when a child he had been treated by hospital physicians for epileptic convulsions and had been cured."

AN ACCIDENT FROM BITING THE FINGER-NAILS.

By JEROME TUTHILL, M.D.,

CHICAGO, ILL.

A novel accident, resulting from a habit of very common prevalence among nervous people, was brought to my notice recently. A young lady presented herself at my office complaining of a constant irritation in her throat. Two weeks previously she had been taken with a severe "sore throat," which was treated by a neighboring physician. Under his care, she says, the inflammation quickly subsided, but there still remained a sensation of irritation. Examination revealed a small fleshy-looking object, about the size of a kernel of wheat, adherent to the tissues posterior to the left tonsil, by one end. The other parts of the throat were normal. The little mass could not be detached by a cotton-covered probe, but by the use of forceps it was easily removed, and on examination proved to be a piece of finger-nail, which had become covered by a cheesy deposit. A broken piece of the nail was also removed from under the mucous membrane at the same spot by a sharp-pointed probe. The patient then confessed to the habit of biting her finger-nails, and, moreover, could remember that a day or two previous to the onset of her throat trouble a piece of nail which she had bitten off had become lost in her mouth, but after it had caused a fit of coughing she had forgotten about it until reminded by my discovery.

ACTIVITY OF THE SCARLET-FEVER POISON AFTER A YEAR.

Dr. J. Brooke, Surgeon U. S. Army, of Fort Monroe, Va., communicates the following case: "A girl aged about eight, living at this place, was some months ago attacked by scarlet fever, the disease running a typical course. For a long time no possible source of contagion could be discovered. The child had not been absent from home, had been with no one lately exposed, and no other case was known to exist anywhere in the vicinity. Subsequently I learned that one of the house-servants had nursed a case of scarlet fever in a distant city just about a year before. After the case terminated she packed some of her things, including some clothing then worn, in a trunk, and left the place. A year later she had the trunk sent to her here, opened it, and took out the contents, the little girl being present and handling the things. Very soon after the latter was attacked, as stated.

"As fixing the period of incubation, it would be interesting to know precisely how many days passed from the time the trunk was opened until the disease appeared; but I was unable to determine that period satisfactorily."

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, August 4, 1888.

CHYLOUS ASCITES.

THIS rare and curious condition has recently been observed by Dr. P. J. Murphy, of Washington, D. C., who has reported the case, and collected the histories of those observed by others. Twenty-nine cases are all that have so far been recorded in medical literature. From these, however, some interesting facts can be drawn with regard to the clinical history of the disorder. As to etiology, hereditary tendency to lymphatic obstruction, as shown by elephantiasis occurring in several members of a family, the female sex, tropical climates, scrofula, and syphilis, are possible predisposing causes. It occurs at all ages, in various occupations, and is usually a complication of some abdominal tumor, or of those diseases causing enlargement of the abdominal lymphatic glands, adhesions, or inflammatory thickening of the intestine and mesentery —notably tuberculosis, peritonitis, and infectious fevers.

In the comparatively few cases in which it may be said to have occurred as a primary affection, it has been due to rupture of the thoracic duct, receptaculum chyli, or a lacteal, by traumatism or muscular exertion after a meal; or, as in one unique case, by obstruction of the thoracic duct by a "soapy mass," apparently analogous to a biliary calculus; or by the perforations of a parasite, probably the *filaria sanguinis hominis*. The latter cause is exceedingly rare in temperate climates. The immediate cause was obstruction of the thoracic duct or lacteals in nine cases, or possibly eighteen, and rupture without obstruction in six cases.

The symptoms in the uncomplicated cases due to rupture are comparatively well marked. The patient, usually after exertion, is suddenly seized with sharp, localized pain, followed by rapid swelling of the abdomen, suppression of urine, nausea, and vomiting, which in some cases is milky and accompanied by a milky diarrhœa.

There is no fever, unless as an accidental complication. Prostration is marked, and, if the case lasts long enough, rapid emaciation ensues. These cases usually recover after one or several tappings. Cases due to occlusion occurring after recovery from peritonitis, or caused by the pressure of a benign tumor, vegetations in the subclavian vein, or a deposit in the thoracic duct, present a somewhat similar history, but are more chronic in their course. They are characterized by dull pain, swelling of the abdomen not so rapid, scanty urine, progressive prostration and emaciation, and occasionally by milky vomiting and diarrhœa. The latter symptoms may occur in any case, and, in conjunction with the signs of peritoneal effusion, are highly diagnostic of chylous ascites.

The diagnosis can be made certain in all cases by tapping.

The prognosis is, on the whole, unfavorable. Out of twenty-two terminated cases death occurred in fourteen, eight recovered, two were relieved.

The treatment in cases due to rupture of a chyle-duct should be rest in bed, with light diet of such food as is digested and absorbed by the stomach, peptonized milk and beef-tea, soft-boiled eggs, whipped raw eggs, etc., given in small quantities at short intervals, and a restricted quantity of water and other liquids, the object being to prevent distention of the lacteals and to favor contraction of the ruptured ends of the lacteal and the formation of a coagulum.

In chyluria one or two drachms daily of gallic acid has been found the most useful remedy, and it would be likely to do good in chylous ascites, especially when caused by filaria. Turpentine is recommended as a remedy for this parasite, and a decoction of mangrove bark (*Rhizophora racemosa*) is a popular remedy in British Guiana. Surgical interference is often needed.

THE DIAGNOSIS AND TREATMENT OF ULCER OF THE STOMACH.

PROFESSOR GERHARDT contributes an interesting article upon the above subject (*Medical Press and Circular*, July 18th). He does not deal with the whole symptomatology of this affection, however, but takes up some especially important features. For example, he states that bleeding occurs in only about one-half (forty-seven per cent.) of the cases. Lebert, whose statistics are usually quoted, in one hundred and four cases met with hæmatemesis in seventy-eight per cent.

The absence of any palpable tumor is usually adduced as an important negative symptom of gastric ulcer. Professor Gerhardt, however, does not place much reliance on this. According to his views four kinds of tumors may be present with gastric ulcer, viz., old ulcers with callous margins, which can often be felt through the abdominal walls, or through the left lobe of the liver. A second kind belongs to the pylorus, and is a tumor of indirect origin, from extraordinary thickening of the pyloric musculature. Circumscribed exudation around perforations gives rise to a third and very rare form; a fourth kind is caused by the crowding of neighboring organs into a large gastric ulcer. In view of all this, the examination of the contents of the stomach is very important.

It has been claimed, of late, as is well known, that in gastric ulcer there is usually a hyperacidity of the gastric juice from increased secretion of muriatic acid. Professor Gerhardt has lately, in twenty-four cases of circular ulcer, found the reaction normal in seventeen cases, but not in seven. Gerhardt concludes that in some cases of gastric ulcer the increase of the hydrochloric acid, which has been generally set up as an absolutely certain sign of the existence of a gastric ulcer, is wanting.

Incidentally it is stated that in sixteen cases of carcinoma observed by him the acid reaction was present in two. The duration of the ulcer was sometimes as long as twenty-five to thirty years, with intervals of good health intervening, so that the patient was looked upon as cured. If a disease of the stomach has lasted three years without the formation of a tumor we are justified in assuming the probability of a gastric ulcer. The seat is generally to be determined by the situation of the pain, which is rarely absent in fresh ulcers. The presence of pain is the more valuable for diagnosis when it is not near the xyphoid cartilage, but at a distance away, when it coincides with tenderness on pressure, comes on at a fixed time after food, and is worse in certain portions of the body. With contraction of the stomach it is generally at the cardiac end; with dilatation, at the pyloric. With tenderness on pressure and the presence of a tumor, one would conclude the case to be one of ulcer of the anterior wall of the stomach, with frequent bleeding one in the posterior wall, because tumors in front are more inclined to perforation, those behind more to hemorrhage. When a patient abstains from food from pain in the stomach, and becomes thin and reduced in consequence, the disease is more probably ulcer, hardly carcinoma, rarely nervous dyspepsia. In the case of recent ulcer great loss of flesh is rare, but emaciation is often observed in old cases; weighing of patients is of great importance from a diagnostic point of view.

The cardinal points in diagnosis, therefore, are hemorrhage, hyperacidity of the gastric juice, long duration of the disease, pain peculiarly located, contraction or dilatation from insufficient ingestion of food.

As regards treatment, diet takes the first place, and, besides this, regard to the etiological condition and the character of the contents of the stomach is of importance. It has been proposed to feed the patient per rectum, but in many cases this is not practicable, as frequently there is a persistent hypersecretion of gastric acid. In recent cases milk diet often suffices, but in old ulcers in which structural changes have taken place milk is frequently not borne at all. Peptones Gerhardt could not praise. Even if they could be taken, they caused a secretion of gastric juices, as Schiff had shown. In cases of profuse hæmatemesis and perforation, on the other hand, they were very serviceable per rectum. Peptones were therefore very suitable for cases in which alimentation by the stomach could not be carried out. In many cases a continuous secretion of gastric juice was present, this was diverted from the ulcer by meat or egg diet. Most physicians therefore recommended a diet mainly animal, meat, milk, or eggs. In cases of stenosis of the pylorus, in which a tendency to lactic and butyric acid fermentations was present, one was compelled to give a diet consisting principally of flesh meat, and to avoid the hydrocarbons as much as possible.

THE DIAGNOSIS OF HUMAN BLOOD.

Dr. Henry Formad contributes an elaborate article upon the comparative morphology of the blood-cells to our always interesting contemporary, *The Journal of Comparative Medicine*. Dr. Formad's studies have not led him to any especially new results, but they confirm views previously expressed as regards the size and appearances of the blood-cells, and some useful directions are given for examining blood-stains and measuring the corpuscular elements. It is a tribute to the accuracy of Gulliver's original measurements, that Formad adopts the figure $\frac{1}{3200}$ inch as the average diameter of the red corpuscle. Our author also supports the claims of the late Dr. J. G. Richardson in regard to the value of very high powers in the measurement of the blood-cells.

For testing the question whether a certain substance is blood or not, the spectroscope and chemical reagents come into play; but for the recognition of human blood the microscope alone is of any value, and the sole method yet found available with this instrument is that of measurement of the corpuscular elements. The differentiation of mammalian blood from that of lower orders of animals is made easy by the fact that in mammals alone is the cell round and non-nucleated. The differentiation between the blood of man and that of lower mammals depends entirely upon the micrometer.

Only the following animals have corpuscles larger than man, *i.e.*, larger than $\frac{1}{3200}$ of an inch; viz., the elephant, great ant-eater, walrus, sloth, platypus, whale, capibara, and (according to Wormley) opossum. Animals the corpuscles of which are slightly below man in size, *i.e.*, having corpuscles from $\frac{1}{3500}$ to $\frac{1}{3200}$ of an inch average diameter, are the seal, beaver, musk-rat, porcupine, monkey, kangaroo, wolf, and guinea-pig. None of these are domestic animals. All other animals, including all domestic animals, have blood-corpuscles of a mean diameter less than $\frac{1}{3500}$ of an inch, and, in fact, those animals which, as a rule, are blamed for blood-stains found on the clothing and apparel of criminals (ox, pig, horse, sheep, and goat), have corpuscles with an average diameter less than $\frac{1}{4000}$ of an inch.

The above facts are formulated as follows:

1. The blood-corpuscles of birds, fishes, and reptiles, being oval and nucleated, can never be mistaken for human blood.

2. Fresh human blood cannot be mistaken, under the microscope, for the blood of any animal the corpuscles of which have a mean diameter of less than $\frac{1}{4000}$ or even $\frac{1}{3600}$ of an inch.

3. (*a*) If the average diameter of blood-corpuscles in fresh blood is less than $\frac{1}{4000}$, then it cannot possibly be human blood.

(*b*). If the diameter is more than $\frac{1}{3500}$, then it may be human blood.

(*c*). If the blood-corpuscles, after exhaustive measurement, give a mean diameter of more than $\frac{1}{3300}$, then it *is* human blood (provided it is not the blood of one of the wild beasts referred to).

The foregoing applies especially to the diagnosis of fresh blood. With regard to dried blood, it is claimed that this can be recognized just as readily, provided it has dried quickly. Blood that has dried slowly undergoes decomposition, and its morphology cannot be made out. A good liquid for remoistening blood is Müller's fluid, but perhaps the best is Virchow's solution, composed of 30 parts caustic potash and 70 parts water. At least five hundred measurements should be made in order to establish the average diameter of the cells.

If the corpuscles are spheroidal from absorption of moisture, or crenated from drying, they may still be diagnosed, because such changes as seen from the tables are the same in the corpuscles of all animals, and have really their proportionate and corresponding ratio of alteration in form and diminution in size, the range or scale of diminution being always alike in the same animal.

The red blood-corpuscles that have become spherical from imbibition of liquid have thus presented in Dr. Formad's experiments the following average diameters in the various animals :

1. Man, $\frac{1}{4300}$ in.
2. Guinea-pig, $\frac{1}{4500}$ in.
3. Wolf, $\frac{1}{4600}$ in.
4. Dog, $\frac{1}{4800}$ in.
5. Rabbit, $\frac{1}{4900}$ in.
6. Ox, $\frac{1}{5600}$ in.
7. Sheep, $\frac{1}{6700}$ in.
8. Goat, $\frac{1}{8100}$ in.

These figures show that the diameter of the artificially spherical corpuscles in each animal is just about one-third less than that of the normal bi-concave or disk-like corpuscles of the same animals.

Dr. Formad is very positive about the value of the microscope and micrometer in determining human blood, taking much the same position as that of Dr. Richardson. Fortunately, it is not very often that the microscope is called upon to decide whether a certain stain is that of human blood or of the blood of a domestic mammal. We hardly think that a jury would convict on its testimony that the corpuscles in a clot were $\frac{1}{5000}$ inch too broad to be those of a dog or guinea-pig. Still, the opinions of experts are becoming more fixed upon this matter, and doubtless Dr. Formad's article will help to give certainty to a hitherto mooted point.

THE DIAGNOSIS DURING LIFE OF CONGENITAL NARROWING OF THE ARTERIES.

It has been long known that the circulatory system is not very rarely subject to congenital defects. Descriptions of these have been given by Morgagni, certain French observers, Virchow, and especially by Beneke.

Dr. Fraenkel has recently attempted to show that congenital narrowness of the arterial system can be diagnosticated during life, and he reports an illustrative case (*Medical Press and Circular*, July 18th). It was that of a powerfully built man, aged thirty-four, who had œdema of the lower extremities, with a pulse-rate of 100 to 112, difficulty of breathing, some bronchial râles, but otherwise no affection of the lungs. Circulatory changes were the marked feature of the case. There was great arterial tension. The heart was displaced to the left and downward ; the apical impulse external to the nipple-line, very broad, high, and resistant, as in insufficiency of the aortic valves. The cardiac sounds were everywhere pure, but the second aortic sound was strikingly accentuated. The quantity of urine was slightly diminished, and it contained no albumen. The patient was of healthy family, and had always been well till his fifteenth year, since which time he had complained of heart trouble and occasional shortness of breath. In his twenty-first year he was a soldier, but had to be discharged as he could not perform the marches, owing to his cardiac trouble. He returned to his occupation, and became gradually worse till he entered the hospital with dropsy. With rest, digitalis, and opium he improved rapidly and was discharged. Diagnosis : Congenital narrowness of the aortic system. While at work the symptoms soon returned, and the patient again entered the hospital, where he died in a short time, with great dyspnœa. The autopsy showed very marked narrowness of the aortic system, commencing at the attachment of the aorta and implicating the whole system.

A second case was that of a laborer, who entered the hospital in 1886 on account of general malaise, but without any particular complaint. All the organs were healthy except for striking symptoms in the circulatory system. The patient, who was of extraordinary robustness, showed abnormal narrowness of the arteries, with marked dilatation of the left ventricle. The apex-beat was very resistant, external to the nipple-line, with accentuation of the second sound. There was absence of history of straining efforts. Although temporary improvement took place under treatment, the lungs became tuberculous, and the patient died of pneumothorax. The autopsy showed striking narrowness of the whole aorta.

Such cases as the above are said to be most frequently met with in women and girls, and are usually labelled chlorosis. In men, on the other hand, who made more demands on the heart, the disease generally led to dilatation of the left and then of the right ventricle. Cases in which such calls were not made on the heart carried the affection to their lives' ends.

In a discussion on Dr. Fraenkel's paper before the Berlin Medical Union, some doubt as to the reality of the condition was expressed, because autopsies, in young people at least, did not show whether the arteries were narrow during life, since the more elastic they were the more they contracted post mortem.

The evidence, however, is on the whole quite strong, that such a condition as Fraenkel describes does exist. Modern science will undoubtedly make it possible, in time, often to recognize it during life.

THE TEMPERAMENTS.

Ancient medicine is thoroughly permeated with the doctrine of humors and of their corresponding temperaments.

Modern scientific medicine, in its desire for exactness and impatience of things that cannot be reduced to some more or less rigid formula, has neglected the subject. We read very little about temperaments, except in essays by lay writers. The study of temperaments has been left chiefly in the hands of persons of a prying but not very scientific turn of mind, and without habits of careful thought.

Physicians learn consciously or unconsciously to recognize temperamental differences, and to suit both manner and medicine to the fact. Perhaps it would be better, however, if in their medical studies they received a little more instruction as to what is really known about temperaments. Our medical forefathers would not have laid so much stress upon the subject if it did not have a scientific basis and some practical bearing.

The foregoing reflections are suggested by the receipt of two small works, entitled "Die vier Temperamente bei Kindern" and "Die vier Temperamente bei Erwachsenen," written by Mr. Bernhard Hellwig.

Perhaps one reason why medical men rarely venture to discuss temperaments seriously is, that authors have so generally disagreed as to the number and names, the combinations and characteristics of the temperaments. Cullen observed only two temperaments, the sanguineous and the choleric ; Begin, quoted by Hammond (*Treatise on*

Insanity, p. 62), recognized three: the sanguineous, the lymphatic, and the nervous. Some writers have made seven temperaments; most authors, however, have made four. These four, according to the old Galenical division, should be the sanguine, the choleric, the melancholic, and the lymphatic; and this is the classification adopted by Mr. Hellwig.

Modern writers generally, however, give a nervous temperament in place of the melancholic. The sanguine temperament approaches nearest to the nervous in the Galenical classification, as described by the author quoted.

Müller, in describing temperaments, said essentially that they represented the reaction of the individual to the environment; and no better definition of temperament can be given than this. Hellwig gives the following curious table, which will be recognized as approximately true. It shows the quickness or feebleness with which persons receive and react to impressions in accordance with the temperament:

Reception.	Reaction.	Temperament.
Strong	Feeble	Sanguine
Strong	Strong	Choleric
Feeble	Strong	Melancholic
Feeble	Feeble	Lymphatic

Examples of "pure" temperaments are comparatively rare. Among one hundred Germans, says Hellwig, one may find ten sanguine, eight choleric, eight melancholic, and five lymphatic. The remaining sixty-nine represent mixtures of two, three, or even all four temperaments. In this country and in the large cities of Europe, a modification of the sanguine, which is called the nervous temperament, has become very prominent. It may be questioned, however, if this nervous temperament is not truly pathological.

THE MISTAKES OF PROFESSOR BLOWMUCH.

"No class of professional men mispronounce the technical words of their calling more commonly than physicians." Such is the indictment made by Dr. Campbell in his work, "The Language of Medicine." This is due partly to defective elementary education, but still more to the ignorance of college professors and orators. Even our dictionaries are not to be trusted, according to Dr. Campbell. Thomas, the most accurate, sometimes errs; Dunglison "commits frequent errors;" and in a small pronouncing medical lexicon a cursory examination has detected no less than forty mistakes.

A very striking and instructive example of the common errors is given by Dr. Campbell in a lecture assumed to be delivered by Professor Blowmuch, of the X. Y. Z. Medical College, before the class of Dr. Hippocrates. The study of orthoepy, it must be remembered, was so highly developed among the Greeks that the mispronunciation of a single word by an orator was greeted with jeers and hisses. Professor Blowmuch's experience is indicated in italics.

"*Gentlemen:* The subject of our dis'course (*hisses*) to-day will be vario'la (*hisses*), rubeo'la (*hisses*), and varioloid' (*hisses*). The ē'tiology (*hisses*) of these affections is not well known. Some regard micrococki (*hisses*) as the *primum causa* (*hisses*), others seek for fomi'tes (*hisses*). It is quite certain, however, that the det'ritus (*hisses*) of the pustules and the fē'tid (*hisses*) odor of the disease contain an infectious principle. When occurring in ad'ults (*hisses*) each vario'lous (*hisses*) pustule leaves a cic'atrix (*hisses*), especially in the fac'ial (*hisses*) tissues, but the ab'domen (*hisses*) may escape. With regard to treatment, use āmmo'nii (*hisses*) ac'etas (*hisses*) for a res'piratory (*hisses*) stimulant, when räls (*hisses*) and brooys (*hisses*) are heard in the lungs. Correct constipation with podoph'yllum (*hisses*) and hyoscyā'mus (*hisses*), removing s*k*ybalæ (*hisses*) by means of an enē'ma (*hisses*). For local antisepsis I prefer iō'doform (*hisses*) and weak solutions of hydrarg'yrum (*hisses*) chlorī'dum (*hisses*) corro'sivum (*hisses*). For asthe'nia (*hisses*) use digitäl'is (*hisses*), and con'ium (*hisses*) may be inserted in ăno (*hisses*). The cadăv'er (*hisses*) should be sent to the crē'matory (*hisses*)."

We suspect that many persons who read over the above will learn with dismay that they have been committing atrocious orthoepic sins during their whole professional life.

It is never too late to learn, however, and we trust that Professor Blowmuch's frequently interrupted lecture may prove of service in teaching a correcter pronunciation of commoner technical words.

INFLUENCE OF REMOVAL OF THE OVARIES ON THE SEXUAL FEELINGS.

A REMARKABLE exhibition of *ex parte* testimony occurred at a recent meeting of the British Gynecological Society, when Mr. Lawson Tait read a paper on the "Influence of Removal of the Uterine Appendages on the Sexual Appetite." Mr. Tait asserts that the ovaries have as little to do with sexual feeling as the front teeth! The other speakers referred in a vague way to the slight influence, sexually, of castration on horses and other animals. One speaker did confess to having a case in which his life was made wretched by the complaints of the patient at having been deprived of sexual feeling. But the general trend of the discussion was to show that öophorectomy was innocuous sexually, if it did not even have an aphrodisiac effect.

Now it is the rule, with hardly any exceptions, in lower animals that removal of the testicles or ovaries destroys the genesic sense (*vide* Colin's "Traité de Physiologie comparée"). The rule holds for human beings in all probability. Certainly it must be so considered until positive evidence accumulates to the contrary. The common opinion and observation of the past cannot be set aside by the flippant judgment of enthusiastic operators on the ovaries. The question must be settled by a careful inquiry of unprejudiced persons, and it should include a statement of the sexual condition at least five years after the operation. Such an inquiry has yet to be made, and meanwhile we trust that gynecologists in general will hold more conservative views than do those of the British Gynecological Society.

DR. KARL KILCHER, of Prague, assistant to Prof. Hlawa, has just succumbed to the effects of an exceedingly repugnant experiment. He had swallowed some blood of a man who had died of typhus fever, and death was caused by septicæmia.

News of the Week.

A Full Report of the Post-mortem Examination upon the Body of the Late Emperor Frederick has been published. The macroscopic changes are summarized as follows: Cancerous destruction of the larynx, with secondary disease of a rather large lymphatic gland at the lower part of the left side of the neck, and a cutaneous nodule on the right side near the wound. Œsophagus unaffected. Inflammatory destruction of the upper portion of the windpipe and the neighboring parts. Numerous bronchiectases, with putrid contents. Near these, broncho-pneumonic suppurating gangrenous patches. The microscopical report signed by Virchow and Waldeyer says:

1. The larger nodule at the base of the epiglottis shows, on the outside, still unchanged mucous membrane with cylinder epithelium, but in the interior, an alveolar structure with epidermoidal contents. The cells of the latter are large and highly developed; concentrically arranged cell-groups were not observed.

2. The cutaneous nodule on the right side of the wound in the neck is covered with extremely attenuated, but otherwise unchanged, epidermis; the cancerous proliferation reaches close to the surface; its chief development is situated in the deeper parts, where also, here and there, "nests," with a concentric arrangement of cells, occur. Some normal constituents, such as sweat-glands. are to be seen between the cancerous masses.

3. The lymphatic gland on the left side of the neck shows the highest degree of change. The normal structure has disappeared, and is replaced by a loose alveolar tissue, the spaces of which are closely filled with epidermoidal cells having large nuclei; many of these cells possess small, bristle-like fringes (*Bürstensäume*).

4. The contents of the bronchial tubes correspond exactly in their composition with the description given by the undersigned Professor Virchow (in his report of May 19th of the present year) on the solid particles found in the expectoration. Moreover, in certain places, a more abundant collection of small, bright fat-globules, like the globules in milk, was observed.

5. In the foci in the lungs were found thick clusters of pus-cells, but no cancer-cells. The natural alevolar structure was still perfectly distinct.

Death Currents.—A series of experiments to determine the death-dealing properties of electrical currents has been made by Mr. Harold P. Brown, of this city. Mr. Brown appears to have shown that the special lethal properties of the electrical current lie in its rapid alternation. A continuous current of 1,410 volts, equivalent probably to 250 or 300 milliampères, had been passed through a dog without causing any accident. On the other hand, an alternating current of 500 to 800 volts instantly killed. The alternating high-tension currents are those used in the arc lights.

The Hudson County Medical Association, formed to prevent the swindling of members of the profession by patrons who can pay but do not, has recently organized and adopted a constitution. It provides for the employment of a collector, in whose hands all questionable bills are to be placed. He is to report those from whom collections cannot be made to the Board of Governors, and the members of the association are to be warned by circular against trusting them.

Our esteemed contemporary, the *Brooklyn Medical Journal*, states that a homœopath of Ithaca, N. Y., recently excited much scandal by confessing to a regular employment of bromide and chloral, in quite large doses. This homœopath, says the *Journal*, evidently is in line with so many of his brethren who have caught the cry of the waiter in the cheap restaurant for dumpling sauce and practise "both kinds with plenty of hard on."

The Cost of the last International Medical Congress amounted to about $17 per member. The cost of the London and Copenhagen Congresses was about $10 a member.

The Children of Ishmael.—At the recent meeting of the National Conference of Charities and Correction, held at Buffalo, Rev. Oscar C. McCulloch, of Indianapolis, read a remarkable paper entitled, "The Children of Ishmael: a Study in Social Degradation." He had upon the stage an immense diagram showing the social condition of thirty families through five generations, numbering 1,692 persons. The history of these people had been followed up for fifty years. It was of the most startling nature. There had been several murderers in the group, and thieves without number. They did not work, they lived by begging and petty thieving. The children died young. Licentiousness characterized all the men and women. From this results mental weakness and general incapacity to work. and this is all met by the benevolent public with unlimited public and private aid, encouraging them in an idle and vicious life. The speaker believed that public relief was in a large degree chargeable with the perpetuation of this stock, and what public relief failed to accomplish private benevolence supplemented. The so-called charitable people who give to begging women and children had a large sin to answer for. Out of these 1,692 persons, Mr. McCulloch said he knew of but one who had risen from them and had become an honorable man. The remedy he indicated was to close up official out-door relief, check private, indiscriminate benevolence or charity, falsely so called, and get hold of the children.

Dr. Joseph Jastrow, a special student of psychology at Johns Hopkins University, has been appointed to the Chair of Experimental and Comparative Psychology at the University of Wisconsin, at Madison.

Advertising Specialists.—The *Journal of the American Medical Association* has officially interpreted the Code of Ethics to allow physicians who follow a specialty to place on their cards "practice limited to," etc. Such notices it is said can be legitimately used as extensively as an ordinary physician's cards. The result is already showing itself in practices which everyone interested in the high standing of the profession must deprecate.

A Number of London Ladies have formed themselves into a "Society for Nursing Sick Bachelors in their Lodgings." The object of this society is to rescue celibate men from the tender care of landladies and charwomen, and while enabling them to "lie by" in their apartments, provide them at the same time with skilful nursing.

Section of the Phrenic.—It is unfortunate that General Boulanger, who has recently suffered from a section of the phrenic nerve, very neatly done by M. Floquet, could not be submitted to the observation of Dr. G. Heinricius, of Berne. This latter gentleman is a scientist who has recently composed an elaborate memoir on the results of cutting the phrenic nerves. Not having the services of an accomplished statesman and swordsman like M. Floquet, the Berne physician had to confine his experiments to dogs and rabbits. He observed that when the phrenic was cut phenomena like those of vagus irritation developed. Whether Boulanger's vagus was upset, the bulletins do not state, but we trust that the results of M. Floquet's interesting section will be given to science.

The Death of Professor Tomassi, of Naples, is announced.

Congress and Quarantine.—The House Committee on Commerce has reported favorably the bill recently passed by the Senate perfecting the quarantine service. It provides punishment for any person trespassing upon any grounds belonging to any quarantine reservation or for any master, pilot, or owner of a vessel entering any port of the United States in violation of the law aiming to prevent the introduction of contagious or infectious diseases into the United States. It also establishes quarantine stations at the following-named places: At the mouth of Delaware Bay, near Cape Charles; at the entrance of Chesapeake Bay; at Key West; in San Diego harbor; in San Francisco harbor, and at or near Port Townsend, Puget Sound. The bill appropriates $542,000 for the construction and maintenance of the above stations and for the maintenance of the Gulf quarantine (formerly Ship Island) $10,000.

Powdered Talc in Diarrhœa was recommended at one of the last meetings of the Hospitals' Medical Society by Dr. Debove, especially for tuberculous patients. The powder is chemically inert, but its mechanical action is very efficient when given in sufficient quantities. He found patients could take as much as six hundred grammes (twenty ounces) in a day, but two hundred are enough for all purposes. The fine powder is to be administered in two pints of milk, the mixture requiring very thorough shaking. With tuberculous patients suffering from obstinate diarrhœa of several months' standing, the success has been in all cases complete, obstinate constipation often resulting.

The Congress of American Physicians and Surgeons.—The Committee of Arrangements announces that the arrangements are sufficiently advanced to assure the success of the First Triennial Session of the Congress of American Physicans and Surgeons, which will be held in the city of Washington, during the 18th, 19th, and 20th of September next. A number of distinguished foreign physicians and surgeons have signified their acceptance of the invitation to attend, among whom may be named Sir Spencer Wells, Sir Andrew Clark, Sir William MacCormac; Drs. W. O. Priestley, William Ord, and Grainger Stewart; Mr. Lawson Tait, Mr. Victor Horsley, Mr. Thomas Bryant, Mr. Thomas Annandale; Professors Ferrier, Esmarch, and Gerhardt; Drs. Rafael Lavista, of Mexico, and J. L. Reverdin, of Geneva. The preliminary programmes of the participating societies have already been published. The classified and final programmes will be printed and distributed at an early day. Places of meeting for the Congress and each of the Societies have been secured, conveniently located, so that members may interchange attendance without annoyance. All the sessions will be open to the profession. The meetings of the Congress will be held in the evenings, beginning at 8 o'clock; on the evenings of the 18th and 19th the meetings will be held in the main hall of the Grand Army Building, 1412 and 1414 Pennsylvania Avenue, and on the last (Thursday) evening in the Hall of the National Museum. During this evening the Army Medical Museum and Library building, alongside of the Museum building, will be lighted and opened for the inspection of the members and invited guests.

The meetings of the special Societies will be held during the day, according to the programme of each, at the following places: American Surgical Association, Main Hall, Grand Army Building, 1412 and 1414 Pennsylvania Avenue; Association of American Physicians, Hall No. 1, Grand Army Building, 1412 and 1414 Pennsylvania Avenue; American Climatological Association, Hall No. 2, Grand Army Building, 1412 and 1414 Pennsylvania Avenue; American Laryngological Association, Hall No. 3, Grand Army Building, 1412 and 1414 Pennsylvania Avenue; American Dermatological Association, Parlor in Willard's Hotel; Association of Genito-Urinary Surgeons, parlor in Willard's Hotel; American Neurological Association, parlor in Willard's Hotel; American Orthopedic Association, Welcker's Hotel, Fifteenth Street, N. W.; American Otological Society, Arlington Hotel, Vermont Avenue; American Physiological Society, Army Medical Museum; American Ophthalmological Society, Arlington Hotel, Vermont Avenue and H Street; American Gynecological Society, Columbian University, Fifteenth and H Streets, N. W.; American Association of Obstetricians and Gynecologists, National Medical College Building, H Street, N. W.

On Monday evening, September 17th, a dinner will be given by members of the Congress to the guests of the participating societies. It will be limited exclusively to members of the Congress and invited guests. Members desiring to participate are requested to notify the Chairman of the Committee of Arrangements. An informal collation will be served at Willard's Hotel on Tuesday evening, after the adjournment of the session of the Congress. A similar entertainment will be served in the National Museum building on Thursday night, after the final adjournment of the Congress. The Secretaries of the special societies are requested to forward to the Chairman the names and addresses of their foreign guests. Guests are requested to notify the Chairman, immediately after their arrival in Washington, of their address and whether they have ladies with them, for the entertainment of whom special arrangements will be made. Members of the Congress and the guests are expected to register. A Registration Office will be opened in a parlor in Willard's Hotel, from which the mail of the members and guests will be distributed, and at which the city residence of each member or guest can be ascertained. All communications to the Committee of Arrangements should be addressed to Samuel C. Busey, M.D., Chairman, 1545 I Street, N. W., Washington City.

Reviews and Notices of Books.

Essentials of Physiology. By H. A. Hare, M.D., Instructor in Physiology, University of Pennsylvania, etc. Philadelphia: W. B. Saunders. 1888.

This is a small manual of 164 pages, arranged in the form of questions and answers, and designed for the use of medical students. We have no hesitation in saying that it is the best condensation of physiological knowledge we have yet seen. Of course the preferable plan is for each student to make out his own condensations as he goes through his larger text-books. All men have not this faculty, however. To such as must depend on others we commend this book.

Diseases of the Skin. By James Nevins Hyde, M.D., Professor of Dermatology, Rush Medical College, Chicago, etc. Second edition. 8vo, pp. 676. Philadelphia: Lea Brothers & Co. 1888.

We must congratulate both the author and publisher on the appearance of this handsome volume. The present edition has been rewritten in most part, and is fully abreast with our most recent knowledge. Classification and nomenclature have been made to correspond to the standard adopted by the American Dermatological Association. Numerous wood-cuts and two colored plates are scattered through the pages. They are unusually clear, and the cuts on the histology of the skin deserve special praise.

The author's ideas on therapy are conservative. He does not regard the internal use of arsenic as by any means a sheet-anchor. He speaks favorably of Unna's muslin-salve preparations, but thinks them too expensive for general use. Dr. Hyde writes clearly and well, and his book is a credit to American medical literature.

Dissolution and Evolution, and the Science of Medicine. By Dr. C. Pitfield Mitchell, London. 8vo, pp. 246. London and New York: Longmans, Green & Co. 1888.

The space at our disposal precludes an adequate review of this book, and we can only indicate its general tenor. It is from the pen of a surgeon engaged in private practice. He is a devotee of Herbert Spencer's "Sympathetic Philosophy," of which he declares evolution and dissolution to be the sustaining elements. He proposes to apply some of the leading generalizations of the new system of thought to the collection of clinical data of medical and surgical practice. Thereby he hopes "to co-ordinate the necessary facts of pathology, and to establish the first principles of treatment." Part I. is styled General Disease. As dissolutional changes are cited inflammation and suppuration, the retrograde metamorphoses (coagulation, gangrene, thrombosis, etc.), the changes induced by animal and vegetable parasites, and finally neoplasms; as evolutional changes, resolution and repair. Part II. treats of Special Disease. As illustrations of dissolution and evolution he mentions interstitial and parenchymatous inflammations, Bright's hepatic cirrhosis, pulmonary inflammation, locomotor ataxia, the fevers, diabetes, and diseases of the mind. Part III. is Implications, and is a practical application of the principles of the author's reasoning to everyday medical work.

The foregoing abstract from the table of contents gives a fair idea of the ground covered. The phraseology is Spencerian throughout. It goes without saying that the thought is profound and the style of argument logical. The author has approached his task in all honesty and seriousness. He concludes that the ruling precept of practical medicine must be the detection and removal of causes. The *vis medicatrix naturæ* is, in the terms of synthetic philosophy, an "organic equilibration."

It may be asked how much does this discussion really accomplish? Does the application of the new philosophical data to current clinical phenomena really assist us in diagnosis and treatment? Here is where different readers of this book would disagree. A scoffer or disbeliever in the Spencerian doctrine would deny that it contributed anything to our positive knowledge. A lover of Spencer would claim that Mr. Pitfield Mitchell had accomplished a most commendable task in showing his professional brethren how to properly classify and consider the facts of clinical medicine and surgery—to trace out hidden relations between causes and effects, and to place therapeutics in general on a more logical basis than it at present occupies.

However, we must confess that we look forward with pleasure to a time when we may examine the book more thoroughly.

The Surgical Diseases of the Genito-urinary Organs, including Syphilis. By E. L. Keyes, A.M., M.D., Professor of Genito-urinary Surgery, etc., in Bellevue Hospital. A Revision of Van Buren and Keyes' Text-book upon the same Subjects. New York: D. Appleton & Co. 1888.

Those who are familiar with the older works of Keyes (Van Buren and Keyes) will scarcely recognize the present treatise. Since 1874 the advances in the department of surgery included under the term genito-urinary have been so considerable that the work before us is practically a new book. The author appears to have been prompted by feelings of reverence for his "dear old master" in calling this a revision of the work alluded to. To mention but a few subjects that are essentially new, we may allude to litholapaxy, suprapubic cystotomy (the modified and revised older operation), renal surgery, the modern methods of dealing with hydrocele, and the radical cure of varicocele.

The profession will give glad and speedy welcome to Dr. Keyes' treatise as it now stands. It may well challenge favorable comparison with similar works by other authors, and if so examined it will not be found wanting in all that is essential to a reliable, readable, and instructive manual on a highly important branch of the healing art.

Health-resorts in Australia. By L. Bruck. Sidney.

This is a tourist's guide-book, and mentions the various places of interest, with particulars as to climate, routes, hotels, medicinal springs, etc.

Stimulants. By J. M. Emerson. New York: Dick & Fitzgerald. 1888.

This is a brief essay on the much-discussed question of alcoholic beverages. The first part is sensible and moderate in tone, and coincides in the main with the general ideas held by physicians concerning the use and abuse of alcohol. In the latter part, the author very strongly advocates the use of pure wines of the lighter varieties as a substitute for alcohol, that is, so far as general consumption is concerned. He advocates this idea so strongly that we almost expect to find at the end an advertisement of some particular vintage. This, however, is not the case. Two of his propositions are strongly open to criticism. One is, that the use of pure wine will often enable a man to give up the stronger liquors. We regard this as a dangerous doctrine for anyone to promulgate. The second is, that the evils of drunkenness are least felt in vine-growing countries; whereas the fact is, that the question of intemperance is becoming year by year a more alarming one in all continental states where the vine is cultivated. The writer alludes to the current questions of high license and prohibition, and is to be commended for the courteous tone of his discussion.

Major George M. Sternberg, Surgeon, United States Army, has been elected an honorary member of the Epidemiological Society of London.

Society Reports.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, June 13, 1888.

W. P. NORTHRUP, M.D., PRESIDENT, IN THE CHAIR.

DR. G. C. FREEBORN stated that Dr. J. M. DaCosta, the Middleton Goldsmith lecturer for the present year, had declined to receive any compensation for his lecture and had requested the Society to apply the amount ($100) to any purpose which might seem desirable. The matter had been referred to the trustees, and they had decided that the most fitting tribute to Dr. DaCosta's generosity would be to purchase some microscopes for the use of the Society, and had requested the speaker to procure them. He had done so, and now exhibited them. He had succeeded in getting two microscopes, one having an Abbé condenser and a $\frac{1}{5}$ objective, the other having no condenser and being of a low power. The microscopes would be engraved with an inscription to the effect that they were the gift of Dr. DaCosta.

DR. J. J. GRIFFITHS presented a specimen of

ACUTE PHTHISIS IN A YOUNG CHILD,

with very extensive deposits of tubercle in the lungs and lymphatic system.

M. ——, aged thirteen months, a foundling, was presented at the Out-door Department of the New York Foundling Asylum, on April 22, 1888, with a history of severe indigestion and diarrhœa of three days' standing. The disease yielded to treatment, and the child remained well until May 17th, on which date she was returned with motor paralysis of the entire left side, including the face. The pupil of the same side was dilated; no paralysis of sensation; moderate diarrhœa; otorrhœa, left side; temperature, 100° F. Six days later it was noted that the left hemiplegia continued, and in addition there was loss of power of the right leg. During the next ten days motion slowly returned to the left arm and leg. The child was returned to hospital on May 30th, and the subsequent history was kindly furnished to the speaker by Dr. Lynde, the house-physician.

Upon admission the cervical, epitrochlear, and inguinal glands were enlarged, there was ptosis of the left lid, and the child refused to nurse.

On June 8th the child was much worse; respiration rapid and labored. There was dulness on percussion anteriorly and posteriorly on the right side, and the respiratory sounds were absent over the whole lung. No retraction of the intercostal spaces; diminution in movement of the chest-wall. The left side was tympanitic on percussion, and bronchial breathing and coarse bronchial râles were heard; marked retraction of the intercostal spaces; temperature, 104° F.

During the four days following, her condition remained unchanged, and she died in collapse, June 12th.

Autopsy, two hours after death. Child fairly well nourished. The brain was markedly anæmic, but otherwise normal. There was a small amount of bloody serum in the pleural cavity. On the right side the superior portion was collapsed and the inferior portion entirely occupied by a large tuberculous deposit, which at several points had broken down into small cavities. Costal pleura normal; pulmonary pleura thickly studded with miliary tubercles. On the left side there were abundant pleuritic adhesions over the anterior and lateral surfaces of the lung, binding it closely to the chest-wall.

In the substance of the entire lung were many deposits of yellow, caseous, tuberculous material, varying in size and consistency. The lymphatic system was largely involved. The cervical, bronchial, retro-peritoneal, inguinal, and epitrochlear glands were all much enlarged and caseous, and many were diffluent at their centres. The liver was anæmic and fatty. The other organs were normal.

The case was interesting chiefly for these reasons: 1, Because of the absence of cerebral lesions to account for the marked hemiplegia which existed; 2, that so extensive a deposit should have been confined entirely to the lungs and lymphatic system, no tubercle having been found in any other part of the body; and, 3, that in this instance epitrochlear enlargement was due to tubercular and not syphilitic disease.

THE PRESIDENT wished to emphasize especially two points of interest in this case. It had been dogmatically asserted that enlarged epitrochlear glands were always an evidence of constitutional syphilis, but here no signs of that disease were discoverable. The second point was the presence of symptoms pointing to cerebral disease, although no brain lesions were found post mortem.

DR. RIDLON thought it conceivable that there was an hereditary syphilitic taint in this case. He had seen a good many children, with a clear hereditary history of syphilis, who had tubercular bone lesions, and he had thought that there might possibly be some connection between hereditary syphilis and tubercular disease in children.

DR. BIGGS had never seen anything exactly like this specimen. The lungs contained large tubercular masses with diffuse miliary lesions.

DR. MYERS presented a

PLACENTA

with the following history of the labor and of the autopsy made on the child:

The mother was admitted to the Foundling Asylum in labor. She had œdema of the legs, and examination of the urine showed a specific gravity of 1.024, acid reaction, granular and epithelial casts, and enough albumin to cause it to solidify on boiling. The quantity passed in twenty-four hours was but four or five ounces.

The labor was rapid, but the head rested at the vulva, and the abdomen caused delay when presenting. The cord was about the neck, but parted on slight traction without hemorrhage.

The placenta was friable and pale, portions of it coming away like cotton-wool when pulled upon, and it was thought to be œdematous.

The child had œdema of the legs, arms, and face, and ascites. It weighed four and one-eighth pounds. Punctate hemorrhages were seen in the skin, especially in that of the legs. The infant was thought to be seven months old. It breathed twelve or fifteen times with assistance, and lived fifteen minutes.

Autopsy.—The abdomen contained eleven and one-half ounces of dark-brownish fluid.

The foramen ovale and ductus arteriosus were open, but the heart was otherwise normal; its weight was three and one-half drachms.

The liver and spleen were somewhat enlarged, and the former contained a number of chalky masses the size of a millet-seed.

There were numerous punctate hemorrhages seen upon the surface of the kidneys and in section of the organs. The tibia was decalcified, and showed normal epiphyseal junctions.

The microscopical examination of the placenta and of the liver of the infant had been made by Dr. Northrup, who reported as follows:

"The chalky, millet-seed-sized masses in the liver were found to be carbonate of lime. The tissue, when hardened and decalcified, showed them to be situated in the veins.

PHLEBOLITHS.

According to Delafield and Prudden 'the changes which occur in a thrombus after its formation may be either in the direction of degeneration or organization. In some cases they seem to undergo a simple shrinkage and decolorization, and to become infiltrated with the salts of lime, forming the so-called *vein-stones* or *phleboliths*' (" Handb. of Path. Anat. and Hist.").

"The capillaries were seen to be filled with white blood-cells, distinctly stained in the microscope specimen herewith shown. The capillaries were dilated and the nearest liver-cells were atrophied. About many veins and phleboliths there was a moderate increase of organized connective tissue.

"Placenta: The shreddy tissue making up the bulk of the body, when removed with care, was found to be a gnarl of fibres. These represented the normal stroma and were expected to tell something of the nature of the process. The stroma was slightly thicker than normal, but well organized, and the vessels with it were normal. The thickening meant diffuse moderate placentitis. The long bones were examined for the condition of the epiphyseal junctions. The tibia was decalcified and sections for the microscope prepared from the upper epiphysis. It was normal.

"The condition of the placenta was not explained by the microscope findings except negatively. There was no evidence of syphilis, and the moderate placentitis would not explain it. The mother was œdematous; the child was in a condition of general anasarca, and in my opinion the placenta was likewise œdematous."

Dr. W. H. Porter thought that there was general dropsy of the whole placental tissue, to which was to be attributed its macerated and atrophic condition. He had seen a similar placenta in a case in which the mother was perfectly healthy, but all the organs of the child were waxy. The cord was œdematous, and the œdema of the placenta resulted in its separation, and in the loss of the child at the seventh month.

Dr. Prudden said that a placenta, resembling this one exactly, had been sent recently to the pathological laboratory of the College of Physicians and Surgeons. No history of the labor had accompanied the specimen. The child was apparently six or seven months old, and had no œdema. Either this condition was not so rare as one would be led to suppose, from the scanty reference to it in the text-books, or else there was a remarkable coincidence in the report of these three cases.

The President did not believe that such cases were at all common. He had examined a great number of abnormal placentæ, but had never before seen one like this. He asked whether there was any objection to an explanation of the condition on the theory of universal œdema of mother, child, and placenta.

Dr. H. M. Biggs presented a specimen showing chronic

CARDIAC THROMBOSIS.

The patient was admitted to Charity Hospital suffering from advanced valvular disease of the heart, having dyspnœa, general anasarca, and rapid and irregular heart action. Under the administration of infusion of digitalis and Hoffman's anodyne he improved for a few days, but then sudden heart-failure occurred and he died.

Autopsy.—There was general œdema, all the large cavities being also filled with fluid. There were evidences of recent pericarditis. The heart was large, weighing about twenty ounces. The mitral valve was the seat of old endocarditis, some calcification being present, and was narrowed. The left auricle was enormously dilated, and contained in its upper part a thrombotic deposit one and a half inch in thickness, the central portion of which had undergone puriform softening, but had not yet opened into the auricle. The right auricle contained a number of small thrombi, varying from the size of a hickory-nut to that of a large walnut. The pulmonary artery was much dilated, and there were numerous points of hemorrhagic infarction in the lungs.

The President showed a piece of intestine which had been placed during warm weather in a quart bottle containing a new preserving fluid compounded by Dr. Prudden. The intestine had been in the fluid for nine weeks, but was well preserved, even showing distinctly the different colors of the fresh specimen.

Dr. T. M. Prudden presented the formula for the

NEW PRESERVING FLUID

referred to by the President.

Water	1,000	c.c.
Common salt	100	gm.
Saltpetre	25	"
Carbolic acid	5	"
Glycerine	15	c.c.
Amylic alcohol	50	"
(or Ethylic alcohol	100	")

Specimens should be first soaked in a strong brine and then placed in a large quantity of this fluid. He believed the mixture would be found to serve a useful purpose in the temporary preservation of gross pathological specimens without changing their color or otherwise altering their general appearance. The mucous membranes were particularly well preserved in the fluid.

Dr. J. Lewis Smith reported a case of

SEPSIS IN AN INFANT.

The child was born in the Foundling Asylum on May 13th. The mother did well, having no febrile disturbance. Before the separation of the cord it was noticed that the child's umbilicus was sore and discharging a little pus. The speaker first saw the umbilical phlegmon when the child was seven days old. At this time three whitish patches, about half the size of a silver dime, were noticed on the hard palate near the velum. There was also purulent conjunctivitis in one eye, notwithstanding the fact that Credé's method of instillation of argentic nitrate solution is always employed in the institution. The faucial trouble increased, and the phlegmon also continued to extend, until the child died at the age of fourteen days. The autopsy was made by Dr. W. P. Northrup, who reported as follows: "The abdominal wall, for the distance of an inch in every direction from the umbilicus, was swollen, the central portion being brown and dry. The peritoneal surface was congested and was adherent to the omentum at the level of the umbilicus. From this point a leash of dilated vessels, an inch in width and between three and four inches long, passed to the transverse colon. The umbilical and hypogastric arteries contained clots. Points of hemorrhagic pneumonia were scattered through all the lobes of the lungs. The stomach showed the lesions of acute gastritis; the mucous membrane was intensely congested, and there was an abundance of tenacious mucus. The kidneys were soft, flabby, and dusky in color. The liver and spleen were normal.

"The anatomical diagnosis was

UMBILICAL PHLEGMON,

peritonitis, acute gastritis, and hemorrhagic pneumonia."

The microscopical and biological examination was made by Dr. T. Mitchell Prudden, who reported as follows:

"The small ragged cavity at the umbilicus contained a moderate amount of pus and of cell-detritus, and enormous numbers of bacteria, of various forms, the spheroidal form predominating. The tissues of the abdominal wall about the umbilicus were infiltrated with fluid, fibrine, and pus. Scattered about in this exudation mass were small spheroidal bacteria. The hypogastric arteries and the umbilical vein were plugged with a clot for from one-half to three-quarters of an inch from their origins. Their walls were greatly thickened by infiltration with inflammatory exudate. Both in the lumina of these vessels along the sides of the clot and in the lymph-spaces in their walls were enormous numbers of small spheroidal bacteria. These bacteria were present in the umbilical vein beyond the limits of the clot, in the direction of the liver.

"The kidneys showed moderate parenchymatous degeneration. The consolidated areas in the lungs were due to a nearly complete filling of the air-spaces and smaller bronchi with blood.

"Cultures made from the inflamed tissue about the umbilicus, and from the edges of the sloughing cavity, showed several species of bacteria common in the air and in the fæces of children. In addition to these, the staphyloccus pyogenes aureus was present in large numbers.

"A set of cultures from the inside of the umbilical vein at a little distance from the sloughing cavity, revealed the presence of staphylococcus pyogenes aureus and streptococcus pyogenes, together with other forms.

"Cultures from the liver showed large numbers of staphylococcus pyogenes aureus, with considerable numbers of a stout bacillus similar to the one abundant in the sloughing cavity.

"From the consolidated regions in the long tissue enormous numbers of bacilli developed in a nearly pure culture, which corresponded in its biological characters to the bacterium lactis aërogenes of Escherich."

Dr. Smith then spoke of the treatment employed, and referred to the disinfection of the room, after a case of contagious disease, by means of burning sulphur. He read a letter from Dr. E. R. Squibb, of Brooklyn, in which the writer stated that

BURNING SULPHUR IS OF DOUBTFUL EFFICACY

as a disinfectant, the weight of the highest authorities in bacteriology being against it, notwithstanding that it is still largely used by very intelligent bodies in large institutions, boards of health, etc., where it would not be likely long to maintain an unearned confidence. Its efficacy would doubtless be greatly increased were the fumes allowed to mingle with the vapor of water discharged at the same time in the apartment. Many bacteriologists have admitted that burning sulphur would kill bacteria, but not their spores.

Dr. Prudden said that the bacteriological examination would seem to show that the child had been the victim of infection with the ordinary "suppurative bacteria," and with the bacteria of fæces. Many of these fæces bacteria were found in the lungs of the infant. As regards the restraining influence of iodoform upon the growth of bacteria, he had mixed bacteria and iodoform together very thoroughly, and had found that the bacteria grew well in cultures made from this mixture.

The Society then went into executive session.

Tympanites and Tympanitis.—The indiscriminate use of these words, says the *Journal of the Amer. Med. Assoc.*, for meteorism or flatulent distention of the intestines is exceedingly common—so common, in fact, that if usage can justify a continuation and sanction of error in the use of words, it may be assumed that it is proper to commit this error. But there is a limit to the justification of error by usage, and the error mentioned is beyond that limit. Tympanites cannot mean inflammation of the lining membrane of the middle ear; tympanitis can mean nothing else. The termination *itis* of the latter word shows that it means an inflammation of the tympanum, while tympanites means a flatulent or drum-like condition of the bowels.

The Percentage of Positively Useful Drugs.—Dr. Uhler writes, in the *Maryland Medical Journal:* Materia medica and therapeutics are more exact than I anticipated, for, after an examination of three hundred and twenty-four remedies described in our text-books, I find that two hundred and eighteen are known to frequently do their work, one hundred and sixteen are untrustworthy, and about one-third of the whole, or one hundred and eight, are very active, and this is probably the correct answer to Professor Bartholow's question of the "Degree of Certainty in Therapeutics."

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twenty-Fourth Annual Meeting, held at Pequot House, New London, Conn., July 18 and 19, 1888.

Wednesday, July 18th—First Day—Morning Session.

(Special Report for The Medical Record.)

The Society was called to order by the President, Dr. W. F. Norris, of Philadelphia.

Dr. H. D. Noyes, New York, read a memoir of the late Dr. C. R. Agnew.

Dr. C. S. Bull, of New York, read a contribution on the

TREATMENT OF MEMBRANOUS OPACITIES IN THE VITREOUS.

Operation by incision with a needle was first performed by Von Graefe. In the experience of the writer the operation had been found useful. Some opacities, as a result of hemorrhage or inflammation of the choroid, sometimes respond to internal remedies, but, as a rule, these fail. By incision of the membrane a direct improvement of vision may be obtained and the process of absorption may be stimulated. Posterior opacities are more easily reached, with less danger to the lens and with more favorable results than in the case of anterior opacities. The author has done this operation in seventeen cases of chronic membranous deposits in the vitreous. In some cases the ordinary discision-needle was used, in others a broader needle, and in a few a slender cataract knife. Cocaine was employed in all cases. The point selected by preference for the introduction of the needle was just in front of the equator of the eye, and below the insertion of the external rectus muscle. There seems in this operation to be no danger of loss of vitreous through the small opening, nor is there danger of hemorrhage. The puncture should be posterior to the ciliary process, and pressure with the forceps should be avoided. Little or no reaction follows the operation as a rule. A protective bandage is required only for a few days. Antisepsis was employed in all cases.

The details of the seventeen operations on fifteen patients were given. Fourteen showed decided improvement in vision; three were failures. There was no loss of vision from the operation in any case. The operation is appropriate in certain cases, but it is wise to wait until all inflammatory symptoms have subsided before attempting any operative procedure. The eye should be absolutely free from all irritation before surgical interference is attempted.

Dr. F. Buller, of Montreal, reported a case of

PULSATING EXOPHTHALMUS CURED BY LIGATION OF THE COMMON CAROTID.

Pulsating exophthalmus occurring spontaneously or as a result of traumatism is rarely met with. The pathology is so well understood that little remains to be done in this direction at the present time. In the matter of treatment there is no rule so firmly established as that much must not be left to the judgment and discretion of the surgeon.

The subject of the paper came under observation May 24, 1888. A young man, aged twenty-eight, fell a distance of twenty feet, striking the right side of head, rendering him unconscious for twenty-four hours. After the swelling had subsided the patient noticed diplopia, one image being higher and less distinct than the other. There was also a loud beating sound in the right ear. Two weeks before coming under observation prominence of the eye was noticed. There was still diplopia, the higher image moving up and down with each heart-beat. Four days before coming under notice the pain became intense. On examination, there was at the inner extremity of the right brow a swelling which imparted a distinct thrill to the finger. There was also a harsh bruit. Pressure over the common carotid diminished the intensity of the thrill and lessened the pulsation.

It was decided to ligate the common carotid in the upper part of its course, and this was done May 25th, two ligatures being applied and the vessel divided between them. The immediate effect was softening of the swelling, partial reposition of the eyeball, great diminution in the pulsation, and disappearance of the bruit. The patient made a good recovery, and left the hospital with very little prominence of the ball; $V = \frac{20}{20}$. movements normal.

Dr. Charles J. Kipp, of Newark, reported a case of

PULSATING EXOPHTHALMUS.

A lady, aged seventy-six, presented herself with the history that shortly after striking the head in a fall, she noticed noise in both ears, followed by protrusion of both eyeballs, the right four-tenths of an inch, the left two-tenths of an inch. There was no marked pulsation, but there was a thrill, and a bruit could be heard over the anterior half of the head. This could be arrested by compression of the right carotid, and partially so by compression of the left carotid. In view of the age of the patient no radical measures were recommended, but it was suggested that pressure be made on the right carotid as often as convenient; iodide of potassium was also given. Three months later the patient stated that the noise had suddenly disappeared. This was followed by disappearance of the exophthalmus, first in the left eye and subsequently in the right. The external appearance of the eyes is now normal. There is, however, a marked pulsation of the right subclavian artery, but no aneurism can be discovered.

Dr. Swan M. Burnett, Washington, gave an analysis of five hundred and seventy-six cases of the

REFRACTION OF HEALTHY HUMAN CORNEÆ, EXAMINED WITH THE OPHTHALMOMETER OF JAVAL AND SCHIOTZ.

These five hundred and seventy-six corneæ belonged to three hundred and one persons, examined within a little over a year by Dr. Burnett. Pathological states of the cornea were excluded for consideration at another time. The corneal refraction was found to be the same in both eyes to within 0.25 D in one hundred and ten persons. The horizontal meridian (to within 5°) was the least refractive (astigmatism according to the rule) in four hundred and twenty eyes. The vertical meridian was the least refractive (astigmatism against the rule) in twenty eyes. In eighty-eight eyes the meridians were oblique. In fifty-eight eyes, the difference in the refraction of the two meridians was less than 0.25 D. In one hundred and one eyes there was emmetropia. The largest number has a corneal refraction of from 44 D to 45 D; the next largest, from 43 D to 44 D; the strongest corneal refraction was 47 D, the weakest 39 D. In fifty-five eyes there was simple myopia. The strongest refraction in the weakest meridian was 47.25 D, the weakest 39 D. The corneal refraction did not, in any considerable number of cases, bear any close relation to the degree of the myopia. Simple hypermetropia was present in fifty-nine eyes. Weakest refraction in the weakest meridian was 40.5 D, the strongest, 46 D. As in myopia, the corneal refraction was no indication as to the degree of general hypermetropia. Myopic astigmatism was found in one hundred and forty eyes. In four eyes the general astigmatism was greater, and in eleven it was less than the corneal. In fourteen eyes the difference in the axes of the corneal membrane and that of the prescribed glasses was greater than 5°. Hypermetropic astigmatism was present in ninety-six eyes. In four eyes the corneal astigmatism was greater, and in two eyes it was less than the general. The axes corresponded in all but nine eyes. Compound myopic astigmatism existed in sixty-three eyes. In all but seven eyes the corneal and general astigmatism corresponded, and in forty-four eyes the axes corresponded. Compound hypermetropic astigmatism was found in fifty-five eyes. In thirty-one, the corneal and general astigmatic meridians corresponded. The corneal and general astigmatism was the same in all but four eyes. Mixed astigmatism was present in eight eyes. In four the corneal and general astigmatism was the same. In two the corneal was less, and in one greater than the general. Corneal and general astigmatic meridians were the same in five eyes.

In forty-two eyes the general astigmatism was against the rule, while in only eighteen of these eyes was the corneal astigmatism against the rule. From examinations under a mydriater the author felt himself warranted in thinking that many cases of lenticular astigmatism are due to an oblique position of the lens.

Corneal astigmatism is, with very few exceptions, according to this rule (vertical meridian) the stronger. From a study of these statistics the author feels warranted in concluding that while the corneal refraction gives no indication of the general refraction of the eye, its astigmatism in the vast majority of cases expresses the general astigmatism both as to degree and direction of its axis, and considers, therefore, the instrument of Javal and Schiotz one of, if not the most important, instrumental means for the diagnosis of the anomaly. He does not think astigmatism more productive of progressive myopia than any other form of ametropia.

DISCUSSION.

Dr. H. D. Noyes of New York: I have used the ophthalmometer of Javal and Schiotz with great satisfaction. The use of this instrument has led me to believe that mixed astigmatism is more common than we usually imagine. I have also noted the influence of the eyelids in altering the curvature of the cornea. I have also satisfied myself that the tension of the eye-muscles modifies the curvature of the cornea. I have also noticed in some cases a pulsation of the corneal reflex, due to the fact that the cornea was so thin that the circulation of the eye impressed itself upon it.

J. B. Emerson, of New York, read a paper entitled

PROGRESSIVE HYPERMETROPIC ASTIGMATISM.

Dr. Eduard Jackson, of Philadelphia, exhibited

A NEW FORM OF CATARACT KNIFE.

It was designed to combine the advantages of the Graefe and Beer knives. The point, resembling that of the Graefe knife, allowed the puncture and counter-puncture to be made in the same way as with the Graefe knife; while the rest of the blade, having the shape of Beer's knife, enabled one to complete the incision as with that instrument. With it the puncture and counter-puncture are completely under control, the flap is completed at a single thrust, the aqueous is not lost until the incision is nearly finished, and the counter-pressure by the back of the knife assists in steadying the eye.

Dr. J. O. Tansley exhibited the following instruments: An improved lachrymal syringe, in which the nozzle ends in a closed bulb, the openings being on the sides of the tube; a clamp to prevent the passage of atropine solutions through the lachrymal duct into the nose in cases where the free use of atropine is called for; an improved lachyrmal probe, and an improved style.

Dr. Samuel Theobald, of Baltimore, exhibited probes made of aluminium.

Dr. Eduard Jackson, of Philadelphia, described a case of

ŒDEMA OF THE CHOROID AND RETINA.

Dr. W. F. Mittendorf, of New York, gave a description of

SYMPTOMATIC MYOPIA.

But little attention has been called to myopia as a symptom of various affections of the eye. It may be caused by traumatism but more commonly by diseased conditions. It may be produced by displacement of the lens forward, more frequently it is due to swelling of the lens accompanying beginning cataract. This is sometimes relieved by the use of concave glasses, very strong glasses being occasionally required. Plastic exudations may also cause myopia, but these usually so interfere with vision that it is impossible to demonstrate the existence of myopia.

Glaucoma, serous choroiditis, and iritis are frequently accompanied with myopia as a symptom. A number of illustrative cases were cited. In these cases the myopia is not permanent, but as the disease disappears the myopia passes away, leaving the refractive condition of the eye the same as before the attack.

Dr. J. O. Tansley, of New York: Some years ago I reported a case of localized exudative choroiditis just beneath the macula, with myopia. The myopia gradually increased as the attack reached its height, and as the inflammation subsided the myopia passed away.

Dr. Carl Koller, of New York: I think that in these cases of myopia in iritis the condition may be due to the irritation of the ciliary muscle. There is hyperæmia of the ciliary body, and as the irides are contracted it is to be supposed that the ciliary muscle is also contracted. Although atropine may be used, there is not full dilatation of the irides. It is therefore reasonable to suppose that the myopia is a result of spastic contraction due to inflammation.

Adjourned till 8 p.m.

Evening Session.

Dr. William Oliver Moore, of New York, reported three cases of

HYSTERICAL BLINDNESS IN THE MALE.

Case I.—Male, aged twenty-five, farmer; family history good. During past two years had suffered with nervous symptoms. Did not smoke or drink. In June, 1886, complained of failing vision in left eye. When seen, June 16th, according to patient's statement, vision in left eye = O; in right eye, normal. Ophthalmoscope showed normal fundus, except a slight patch of opaque nerve-fibre near the papilla. Testing with prism and candle gave double vision, as did pressure on one eyeball. The patient was informed that treatment by electricity would cure him in a few days. A severe faradic current was applied, causing the patient to jump from his chair, exclaiming that there already was improvement. In ten days $V = \frac{20}{XX}$; emmetropic.

Case II.—Male, aged twenty-two, student and farmer; fine-looking. History of insanity in the family. Eighteen months previous to coming under observation atropia had been instilled by a physician to determine whether or not glasses were required. He thought from the effect of the atropine that he was going blind. He then put on smoked glasses, subsequently bandages, and kept in a dark room. He would not open the lids, and declared that he was blind. For ten months he kept in a dark room with covering over the eyes. On examination the lids were closed, but not by spasm; the cornea clear; V = O. Ophthalmoscopic examination under ether: normal fundus. Hysterical blindness was diagnosed, and a favorable prognosis given. Canthoplasty was then performed. Coming from the ether the patient opened his eyes and evidently saw clearly. He was told that the cause of the disease had been discovered and that he would be well in a few days. In two days he was walking around without glasses. Has remained well since.

Case III.—Boy, aged fifteen. Developed blindness in right eye after a disappointment at school. Normal appearance of eyes. Tests with prisms and colored glasses showed that vision was present. Ether was administered and patient assured that he would be well, and under electricity recovery was rapid.

Dr. Charles A. Oliver, of Philadelphia, gave a description of a series of tests for the

DETECTION AND DETERMINATION OF SUBNORMAL COLOR PERCEPTION (COLOR-BLINDNESS), DESIGNED FOR USE IN RAILWAY SERVICE.

It is a well known fact, both from theoretical and practical standpoints, that many "color-blinds," especially those of medium grades, have the power of differentiation, even by daylight, of the most difficult colors, when placed at ordinary metre distance of wool selection employed in the detection and determination of color-blindness. The writer, recognizing the possible dangerous consequences of this partial color-blindness in those employed on railways and in the marine and naval service, where the safety of lives and the protection of property is ofttimes solely dependent upon proper recognition of color at great distances, and frequently through the intervention of more or less translucent media, was led to combine two modifications of his method of color selection with a simplified plan of the former procedure, by which the candidate is placed in the actual position of after-work, and under exactly similar circumstances as during employment. The method is divided into three parts.

First. The selection and registry of a definite number of loose wools from twenty-three pure and confusion match skeins thrown upon a dead black surface at one metre distance.

Second. The selection and registry of the same number of similar reflected colors, under various intensities of diffuse daylight stimulus, placed at distances requisite for safety.

Third. The selection and registry of transmitted colors, under various intensities of artificial light stimulus, placed at distances requisite for safety.

In addition to the advantages shown to refer to the first test alone, the method has the following additional ones:

1. Much faster in time than any other method. 2. The selection of loose wools at a distance. 3. No necessity for an expert except in doubtful cases. 4. Employment of the same character of signal for testing as is used in daily routine. 5. Placing the eye, during testing, at a distance necessary for future safety. 6. Bringing the eye during testing directly before the true condition of weather experienced whilst it is upon duty. 7. Test and match colors all graduated in proportionate size.

Dr. Charles A. Oliver, of Philadelphia, gave a case of

EMBOLISM OF THE CENTRAL RETINAL ARTERY.

The patient, a young man, was seen October 5, 1887. Twenty-six hours previously while slowly walking in the shade, he was suddenly seized with blindness in the left eye. There were no other symptoms, and there had been no previous illness. The right eye was normal. Ophthalmoscopic examination of left eye showed clear media, nerve substance of a gray tint, and swelling of the retina. All the retinal vessels were reduced in size. The veins were somewhat contracted, especially toward the nerve entrance. The characteristic cherry spot in the macular region was distinct. There was a small hemorrhage out from the disk. Careful physical examination failed to reveal any lesion in other parts of the body. The case was kept under observation for some time, but there was no return of vision, the patient remaining completely blind in the left eye.

DISCUSSION.

Dr. H. D. Noyes, of New York: The result of autopsies shows that the great majority of these cases are really due to thrombosis and not to embolism.

Adjourned until Thursday morning.

Thursday, 19th—Second Day—Morning Session.

Dr. Samuel Theobald, of Baltimore, described a case of

DOUBLE CONGENITAL IRIDEREMIA

in a child whose mother exhibited a congenital coloboma of each iris.

James O———, aged eighteen months, was seen December 9, 1887. His mother brought him on account of the red appearance which the pupils presented. Upon examination, besides a congenital squint of the left eye, complete absence of each iris was discovered. The lenses were clear, and there seemed to be, at least in the right eye, fairly good vision. The interest of the case lies in the fact, accidentally discovered, that there existed in the mother a congenital coloboma of each iris. In her right eye the coloboma was large, its direction being directly upward; in the left eye it was somewhat smaller, and was in an upward and outward direction. In neither eye was the choroid involved in the congenital defect. The mother volunteered the statement that an older child had had a similar appearance of the eyes, so that it is probable that to this mother, with congenital coloboma, there were born not only one but two children with absence of the irides.

DISCUSSION.

Dr. David Webster, of New York. I think that the direction of the coloboma in the mother's eyes was unusual. I have seen a number of cases of congenital coloboma of the irides, but I do not recall an instance in which the coloboma was upward. It is almost always downward.

Dr. T. Y. Sutphen, of Newark, N. J., reported the results of three operations of

PUNCTURE OF THE RETINA FOR DETACHMENT.

A male, aged sixty-two, sought treatment, April 1, 1887, for a cloudy appearance before the right eye. This he had noticed only a few days. He was near-sighted, but had never used glasses. Examination: R. S. = $\frac{15}{100}$, raised to $\frac{15}{20}$ by $-\frac{1}{16}$; field of vision defective downward and toward the median line. Tension slightly diminished. L. S. = $\frac{15}{100}$, raised to $\frac{15}{15}+$ by $-\frac{1}{16}$. Ophthalmoscope showed myopia with choroiditis in both eyes. In the right eye the retina was found detached in its upper and temporal portion. The patient refused to undergo vigorous treatment in bed. He was given iodide of potassium in gradually increasing doses, rest being enjoined.

Five months later the patient returned with commencing detachment in the upper and temporal portion of the left retina. He was then kept in bed for two weeks with the eyes bandaged, while profuse diaphoresis was frequently induced, but without benefit. He was then sent to the country, the iodide being continued. By December 1st there was in the right eye only perception of light; in the left there was vision, confined to the outer and lower field. On this date puncture of the retina from beneath the detachment was made. Thorough antisepsis was employed, cocaine was instilled, a sickle-shaped needle was thrust into the globe between the insertion of the external and inferior recti muscles, on the equator, and on a plane with the lens. It was pushed onward until it was thought that the retina had been pierced. It was then withdrawn with a sweeping motion, the object being to enlarge the opening in the retina. Atropine was instilled, the eyes bandaged, and the patient ordered to keep quiet. The following day the subretinal fluid had disappeared, field of vision was normal, a red reflex was obtained from the fundus in every direction, and the patient could distinguish large objects. Bandage was reapplied. Two days later, patient could count fingers, at twelve feet, the retina appeared in its normal position, but the vitreous was quite cloudy. The vision continued steadily to improve.

December 10th.—A similar operation was performed on the left eye. Two days later there was marked enlargement of the field of vision, but some detachment was still to be seen on the temporal side.

December 16th.—The field of vision in both eyes normal. No detachment of retina in either. The patient remained in bed twenty-eight days.

February 10th.—Detachment began to reappear in the left eye, and by March 3d it was as great as before. Needling was again performed with the escape of very little subretinal fluid.

March 5th.—Field again normal.

April 1st.—Partial return of detachment in left eye.

July 6th.—Seven months after first operation: S., R. = $\frac{15}{100}$, raised to $\frac{15}{40}$ by $-\frac{1}{20}$, no return of detachment, field of vision normal, blindness for red. In the left eye almost complete detachment of the retina.

After referring to the history of the operation the speaker said that the interesting facts were these: The apparently perfect safety of the operation under modern antisepsis; one success and two failures under exactly similar conditions, barring the escape of the fluid outward in the successful case; encouragement to try this operation in otherwise incurable cases; the absolute freedom from all reaction. The best results will probably follow where the operation follows closely upon the subsidence of the acute affection causing the detachment. The chances of success are increased by a free flow of fluid outward. It was suggested that a narrow Graefe knife might be used after accurately measuring the depth of the detachment, provided the point be so directed that the wound in the retina shall be directly opposite the scleral puncture.

Dr. F. P. Copron, of Providence, reported

A CASE OF GLIOMA.

The patient was a child, aged three and one-half years. The growth was removed, but has since involved the submaxillary glands and the glands in the neighborhood of the ear. Photographs showing the appearances were presented.

Dr. D. B. St. John, of Hartford, Ct.: I would ask whether aid in the diagnosis between glioma and other affections is afforded by attention to the state of the tension.

Dr. David Webster, of New York: I think that I have never been able to detect any increase of tension until the second or inflammatory stage has been reached. Then there is always, I think, increase of tension. In at least two cases I have diagnosed glioma from the history with the existence of increased tension, when no tumor could be discovered.

Dr. Swan M. Burnett, of Washington, showed

MODELS EXHIBITING REFRACTION BY CYLINDERS.

It was shown how the refraction and focal line change with the variation in the strength of the lens and with the alteration of the angle of crossing of their axes. The models were made at his suggestion by Mr. C. F. Prentice, of New York. Diagrams were exhibited showing by geometrical construction how it was possible to tell the course of any given ray after its refraction by any two cylinders of differing power and at any angle of crossing of their axes. A formula applicable to any axis of crossed cylinders, calculated by Mr. Prentice, was also shown.

Dr. B. Alex. Randall, of Philadelphia, exhibited some drawings showing anomalous

OUTGROWTHS UPON THE OPTIC DISK,

and also drawings of anomalies of the retinal vessels.

Dr. Eduard Jackson, of Philadelphia, pointed out the inconveniences and errors arising under the present method of designating the

STRENGTH OF PRISMS,

and recommended their designation by their refractive powers as much more accurate.

A committee, consisting of Dr. H. D. Noyes, Dr. Eduard Jackson, and Dr. Swan M. Burnett were appointed to take the matter into consideration and report at the next meeting.

Dr. David Webster, of New York, described an

EXTRACTION OF A PARTIALLY ABSORBED CALCAREOUS LENS.

March 15, 1888.—C. C——, aged twenty-three, consulted Dr. Agnew and the author at the Manhattan Eye and Ear Hospital. She had phthisis bulbi in the left eye, and in the right were the calcific remains of a mostly absorbed lens, with a discolored atrophic-looking iris attached to the membranous mass by numerous adhesions. Visual field good. V=fingers at two feet. The vision of left eye had been lost through a blow with a whip at the age of two years. A catarrh developed in the right eye some time afterward. Seven years ago (1881) her sight having been lost four months, both eyes were operated on by a surgeon in another city several times. Violent inflammation followed one or more operations on each of the eyes. Eighteen months ago another needling was done by another surgeon, by which sight was somewhat improved. The atrophic eye, of late, has been painful and tender on pressure. March 16th, Dr. Agnew enucleated the atrophic eyeball. A calcific plate was found in the choroid, and a small, calcareous lens. While the patient was still under ether he did an iridectomy on the right eye. April 27th, Dr. Webster divided, with Knapp's knife-needle, two or three of the adhesions which were on the stretch. At least one could be heard to snap when cut. An attempt to penetrate the thinnest-looking portion of the membranous mass failed. There was considerable effusion of blood, which was soon absorbed.

May 14th.—An attempt to remove the pupillary obstruction with a sharp hook failed. Very little reaction.

June 6th.—With a keratome bent on the flat a wound was made as for iridectomy on the supero-nasal corneal border. The pupillary obstruction was drawn out and cut off close to the cornea. Not a drop of vitreous escaped. There was some pain in the eye for three or four hours, probably the reaction from cocaine. Four days later pain again appeared, and was relieved by iced cloths.

June 18.—Fundus normal, no floating bodies in the vitreous, but the remaining portion of the pupillary membrane, which by the way was very thick, and so tough that the iris scissors would scarcely cut it, extends backward horizontally and flops up and down with the movements of the eye.

June 22d.—$V = \frac{20}{20}$ with $- \frac{1}{32}$. Reads Jaeger No. 1 with $+ 1/2\frac{1}{4}$.

June 26th.—Discharged, wearing the above spectacles.

Dr. Samuel Theobald, of Baltimore, exhibited an unusually long cilium. The hair was over an inch in length, and was removed from the eyelid of a young lady suffering with some conjunctival irritation; the other cilia were of the usual length.

The officers for the ensuing year are: *President*, Dr. W. F. Norris, of Philadelphia; *Vice-President*, Dr. Hasket Derby, of Boston; *Corresponding Treasurer*, Dr. J. S. Prout, of Brooklyn; *Recording Secretary*, Dr. Samuel B. St. John, of Hartford.

It was decided to hold a special meeting, for the consideration of scientific matters only, September 19, 1888, at the Arlington Hotel, Washington, D. C.

The regular meeting will be held the third Wednesday in July, 1889, at the Pequot House, New London, Conn.

Adjourned.

The Best Method for Curing Fistula in Ano, according to Dr. Brinton, without the use of the knife, is by passing a silk or gum-elastic cord through the fistulous tract and, bringing it out of the rectum, tie it. This will excite inflammation, and the cord will gradually cut its way out, followed by granulation. By this method the patient can be cured while following his ordinary occupation. —*College and Clinical Record.*

The Antagonism of Poisons.—At the Paris Society of Biology, M. Roger gave the results of a series of observations made by him bearing on the alleged antagonism of certain poisons. (*The Medical Press*). He first ascertained by experiment the toxic dose of individual drugs, and then gave mixtures of any two. He found that animals succumbed to the effect of a mixture of morphine and atropine long before the fatal dose of either drug alone had been reached, and the same thing was observed with a mixture of atropine and quinine, or quinine and morphine. In every case the two substances produced their own particular effects, and, with the exception of a mixture of chlorate of potash and opium, a much smaller quantity of the double poison was required to kill than when either drug was employed singly.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 29 to August 4, 1888.

Magruder, D. L., Surgeon, is granted one month leave of absence, to take effect on or about August 13, 1888. Par. 11, S. O. 171, A. G. O., July 25, 1888.

White, Robert H., Surgeon, is relieved from duty with Battalion First Infantry, at Santa Barbara, Cal., and will proceed to Angel Island, Cal., on public business; on the completion of which he will stand relieved from duty in this Department. Par. 4, S. O. 43, Headquarters Department of California, July 17, 1888.

Munn, Curtis E., Assistant Surgeon, will proceed to Santa Barbara, Cal., and report to Commanding Officer of the Battalion of First Infantry for duty. Par. 3, S. O. 43, Headquarters Department of California, July 17, 1888.

Cochran, John J., Assistant Surgeon, will proceed to Benicia Barracks, Cal., on public duty; on completion of which he will return to these Headquarters. Par. 1, S. O. 44, Headquarters Department of California, San Francisco, Cal., July 20, 1888.

Robertson, Reuben L., Assistant Surgeon, is relieved from duty at Fort Keogh, Mont. Ter., and will report to the Commanding Officer at Fort Buford, Dak., for duty at that post, and by letter to the Commanding General, Department of Dakota. S. O. 167, A. G. O., July 20, 1888.

Jarvis, N. S., Assistant Surgeon, is granted one month leave of absence on Surgeon's certificate of disability, with permission to go beyond the limits of the Department. By par. 1, S. O. 90, Headquarters Department of the Missouri.

Johnson, Henry, Captain and Medical Storekeeper. Leave of absence granted for one month and fourteen days, from August 1, 1888. S. O. 170, Headquarters of the Army, A. G. O., July 24, 1888.

Wolverton, William D., Major and Surgeon, is relieved from duty at Washington Barracks, D. C., and ordered to duty at Fort D. A. Russell, Wyo. By par. 13, S. O. 173, A. G. O., July 27, 1888.

Gardner, William H., Major and Surgeon, is relieved from duty at Fort McHenry, Md., and ordered to duty at Washington Barracks, D. C. By par. 13, S. O. 173, A. G. O., July 27, 1888.

Caldwell, Daniel G., Major and Surgeon, is relieved from duty at Fort D. A. Russell, Wyo., and ordered to duty at Jefferson Barracks, Mo. By par. 13, S. O. 173, A. G. O., July 27, 1888.

Byrne, Charles B., Captain and Assistant Surgeon, is relieved from duty at Washington Barracks, D. C., and ordered to duty at Fort McHenry, Md. By par. 13, S. O. 173, A. G. O., July 27, 1888.

Ewing, Charles B., First Lieutenant and Assistant Surgeon, is relieved from duty at Fort Lewis, Cal., and is ordered to duty at Washington Barracks, D. C. By par. 13, S. O. 173, A. G. O., July 27, 1888.

Official List of Changes in the Medical Corps of the United States Navy for the week ending July 28, 1888.

Penrose, Thomas N., Surgeon. Detached from Navy Yard, Boston.

Parker, J. B., Surgeon. Ordered to the Navy Yard, Boston.

McCormick, Albert McD. Commissioned Assistant Surgeon in the Navy.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending July 28, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	38	13
Scarlet fever	119	17
Cerebro-spinal meningitis	4	3
Measles	199	10
Diphtheria	101	36
Small-pox	0	0
Yellow fever	0	0
Cholera	0	0

We Have a Swinburnian Medical Poet in the person of Dr. James Newton Mathews, who read the following melodious and alliterative verses at the banquet given by the Marion County Medical Society to the Indiana State Medical Society. It is entitled "Ballad of a Busy Doctor:"

When winter pipes in the poplar-tree,
  And soles are shod with the snow and sleet—
When sick-room doors close noiselessly,
  And doctors hurry along the street;
When the bleak north winds at the gables beat,
  And the flaky noon of the night is nigh,
And the reveller's laugh grows obsolete,
  Then Death, white Death, is a-driving by.

When the cowering sinner crooks his knee
  At the cradle-side, in suppliance sweet,
And friends converse in a minor key,
  And doctors hurry along the street;
When Crœsus flies to his country-seat,
  And castaways in the garrets cry,
And in each house is a "shape and a sheet,"
  Then Death, white Death, is a-driving by.

When the blast of the autumn blinds the bee,
  And the long rains fall on the ruined wheat,
When a glimmer of green on the pools we see,
  And doctors hurry along the street;
When every fellow we chance to meet
  Has a fulvous glitter in either eye,
And a weary wobble in both his feet,
  Then Death, white Death, is a-driving by.

ENVOY.

When farmers ride at a furious heat,
  And doctors hurry along the street,
With brave hearts, under a scowling sky,
  Then Death, white Death, is a-driving by.

The Treatment of Summer Diarrhœa at the Wilson Sanitarium, Baltimore, as described in the *Maryland Medical Journal*, is as follows: In acute diarrhœa with vomiting of milk, the child is at once taken from the breast or bottle, and no food except beef-tea is given to it for twenty-four hours. Small doses of calomel—gr. $\frac{1}{12}$ to gr. $\frac{1}{6}$—are administered hourly for a day or two, to quiet the stomach and to excite the secretion of the liver. At the end of twenty-four hours sterilized milk is given. If the vomiting returns the milk is stopped and beef-tea is resumed for twenty-four hours, when milk is once more given. No artificial foods are used in the Sanitarium. Irrigation of the lower bowel is practised two or three times a day, if it does good. In chronic cases resorcin, gr. ij., with tr. opii deodorata, gtt. $\frac{1}{2}$, is given every two or four hours. When vomiting proceeds from nervousness, sodii bromidi, gr. ij., and chloral hydrate, gr. j., are administered every two or four hours to a child of six months. This same prescription is used for sleeplessness. As a rule, no further medication is needed. For irrigation of the bowels a fountain-syringe full of tepid hydrant water is connected with a soft-rubber catheter about fourteen inches long, and this catheter, oiled, is passed gently to its full length into the rectum and descending colon, the water—a gallon or more—being allowed to follow into the bowel and out again by the side of the catheter. This irrigation is painless and often aids greatly in recovery, especially in severe cases resembling cholera infantum.

Treatment of Colds and Bronchitis.—In the *Therapeutic Gazette*, Dr. H. C. Wood discusses in a leading article the treatment of colds and bronchitis. When the cold is a wide-spread general one, involving the whole body in a condition which he regards as a form of subacute rheumatism, with aching pains and general wretchedness, he advises a free jaborandi sweat, followed by a few full doses of quinine. This, he says, will often liberate the sufferer at once, especially if the sweats are aided by mercurial or other purgation. For coryza, he says bismuth and cocaine injections into the nose almost invariably bring relief, though a vigorous dry shampoo may effect the same result. In bronchitis, he says, the so-called expectorant remedies are of course indicated. These he divides into three groups: First, the narcotic expectorants, which are to be employed to allay excessive cough and quiet nervous irritability; second, the sedative expectorants to be used in the first stages of a bronchitis, to facilitate secretion and expectoration; third, the stimulating expectorants, useful in the advanced stages of a bronchitis when expectoration has already become free. The ordinary narcotics, such as morphine and hyoscyamus, and the advantages and difficulties attending their use, he thinks are well known. Chloroform, however, he regards as one of the most valuable remedies that we have for quieting cough. In nervous or hysterical men or women, often the best expectorant mixture is one composed of pure narcotics. A very good home-made mixture for this purpose is one containing: Whiskey, paregoric, glycerine, of each, f ʒ ij.; chloroform, ♏ xxx. M. Shake well before using, and take in teaspoonful doses *pro re nata*. This mixture has, he says, enabled patients to secure many a night's rest, by keeping a little bottle of it, tightly corked, at the bedside, and sipping it when necessary. With regard to the use of hydrocyanic acid as a sedative, he seems to think that its action is so fugacious as to be untrustworthy in ordinary safe doses; while wild-cherry bark preparations he rejects as certainly useless. The older depressing expectorants he thinks have little power, unless given in nauseating doses, and in their stead he has come to use very largely the citrate of potassium. Of the following prescription, he says he thinks anyone who will use it will never give it up, unless some remedy of greater power be discovered: ℞. Potas. citr., ℥ j.; succi limonis, f ℥ iss.; syr. ipecac, f ℥ ss.; tr. opii cam., f ʒ iij.; syrup, q. s., ad f ℥ iij. M. Sig.—Dessert-spoonful every two hours. This dose is for robust men and must be varied according to the strength and peculiarities of the individual patient. Of the older stimulating expectorants the only ones in which he still places confidence are the muriate of ammonium, and syrup of garlic. When the citrate of potassium mixture fails, he habitually resorts to the muriate of ammonium, and has often seen very good results from its use. It may be given in capsules if the stomach is very sensitive, each capsule to be followed by a drink of water. The following furnishes the best disguise for the taste of the drug that he has been able to concoct: ℞. Ammonii chloridi, ext. glycyrrhizæ, āā, ʒ iss.; glycerini, f ℥ ss.; mucil. acaciæ, f ʒ ij.; syrupi, aquæ, q. s., ad f ℥ iij. M. Sig.—Dessert-spoonful every two hours.

Oliver's Test for Bile in Urine is performed as follows: Make a solution containing thirty grains of pulverized peptone, four grains salicylic acid, thirty minims acetic acid and eight ounces of distilled water. Secure perfect transparency by repeated filtration. Pour twenty minims of urine into one drachm of the test-solution, and if bile is present an opalescence appears proportionate to the amount present.

THE RADICAL CURE OF HERNIA.

By DUDLEY P. ALLEN, M.D.,

VISITING SURGEON TO CLEVELAND CITY HOSPITAL AND TO CHARITY HOSPITAL, CONSULTING SURGEON TO ST. ALEXIS' HOSPITAL.

The object of this paper will be to consider briefly the importance of some procedure for the cure of hernia, and the difficulties to be overcome in its accomplishment. Also, to present two unusual cases successfully operated upon.

It is no part of our purpose to enter upon a history of the various methods that have been proposed, through all the centuries, for the cure of hernia. The modern development of abdominal surgery places operations for the cure of hernia upon a new basis. The history of operations, as at present practised, dates back but a few years. That some method of cure is of great importance is evident. The frequency of the deformity, and the dangers to which its possessors are subjected, are known to all. Certainly there are few ailments which so impair the comfort and endanger the life of mankind.

Innumerable methods of cure have been proposed. The method of Wood, of London, of suturing the pillars with a silver wire, is, perhaps, the most successful of those which propose to relieve the difficulty without opening the abdominal cavity. Since the simple opening of the abdomen entails so little danger *per se*, the method of Mr. Wood has lost what was the chief argument for its support.

Two methods may properly claim our attention at the present time: First, that of opening the abdomen, dissecting from its attachments the hernial sac, and, folding this upon itself, returning it within the abdominal walls, so that, resting just outside of the peritoneum, it makes a convexity where the hernia formerly existed. This is the well-known method of Macewen, of Glasgow. Second, the method of extirpating the hernial sac, by ligation as close as possible to the peritoneal cavity, and uniting the opening in the abdominal wall. This method has been presented by Lucas Championnière, of Paris, perhaps as carefully as by any one.

It would be interesting to compare the opinions of these two most eminent surgeons on those points in which they agree, and also those in which they differ, but this would take us beyond the limit which we have assigned ourselves. We shall presuppose that those of this body who are interested in the subject of operations for the radical cure of hernia are already familiar with the methods in vogue, and we shall proceed to the consideration of those points in the operation upon which depend success or failure.

The chief dangers in operations for the radical cure of hernia have been considered to be those dependent upon opening the abdominal cavity. Peritonitis is as fatal now as at any time in the history of surgery, and, we suspect, as frequent, if not more so. Adherent omentum and intestines may seriously complicate operations. These are difficulties, however, which can be overcome successfully by operators skilled in the technique of abdominal operations.

We do not wish to be understood to underestimate the dangers of the operation in incompetent hands. Personally, we are doubtful if the length of life of the human race has, up to the present time, been prolonged by the various operations practised upon the abdomen. Laparotomy has come to be looked upon as so devoid of danger that it is performed by every one who chances to meet with a case which he thinks may possibly require it, and this, too, without a familiarity with those details, and a knowledge of possible complications, which make operation safe. I do not believe anyone should undertake to operate for the radical cure of hernia who is not a competent operator in the whole field of laparotomy. The difficulty inherent to all operations for the radical cure of hernia is in forming a new wall sufficiently strong to resist the impulse of the gut against it. What the power of the gut is to force itself through any aperture, however small, was remarkably illustrated to us in a laparotomy upon a fat woman, in whom complete anæsthesia was difficult to obtain. In pushing the hand down to the loins, for the purpose of feeling the kidneys, the fingers were repeatedly separated from each other by the intestines forcing themselves between them, and it was absolutely impossible to hold the fingers together. It is thus evident that if any depression or weakness remain at the point of operation, the gut will be liable to force itself into this, and cause recurrence of the hernia. How these difficulties may best be overcome will be considered a little later. It may be proper now to consider the important points connected with the operation.

To have the gut free from air and fæces is a great convenience to the operator, preventing the tendency of the gut to escape from the opening of the hernia while operating. In operating for hernia, as well as in all laparotomies, it is well to give a full dose of castor-oil twenty-four hours before operating. Follow this by an enema at the time of the first passage from the bowels, and again two or three hours before the operation. After administering the oil give only an easily assimilated diet, and give nothing beyond a cup of broth on the morning of the operation. The patient should be scrupulously clean, and the parts to be operated upon should be most thoroughly washed, shaved, and washed again; and then disinfected and surrounded by towels soaked in a disinfectant. To discuss the question of antiseptics in connection with this operation would take us too far. It is our belief that its relation to this operation is the same as to other laparotomies. Perhaps it is more important, since the surroundings are especially prolific of secretory and septic material. While we do not say that the employment of antiseptics is an absolute necessity, we do consider them highly desirable. By this we mean an antisepsis which is rigorous and complete in every detail.

In operating, a complete anæsthesia is of great importance, since, if incomplete, the escape of abdominal contents from the ring may at any moment seriously embarrass the operator.

The complete dissection of the sac of the hernia from its surroundings is desirable. If the lower part of the sac remain *in situ* it may form a cyst. The removal of the upper portion is highly important, since, if this is not done, it prevents the formation of as firm a cicatrix as would otherwise be obtained.

The opening of the sac has been looked upon by some as a thing to be avoided. We believe emphatically that it should be opened. The increased danger from this is, we believe, *nil*. By opening it the operator is enabled to see whether or no there are adhesions of gut or omentum, and successfully to care for them. It is our practice in operating to open the sac of the hernia about one inch below the abdominal opening, see that it is empty, and then to separate this part of the sac from its surroundings and from the cord, and clamp it with a pair of forceps above the point where it is opened. Thus the abdominal cavity is closed, and the operator can proceed to loosen the adhesions of the remaining portion of the sac. The dissecting of the sac from the surrounding tissues and from the cord is usually not difficult, and we have commonly succeeded best with the finger-nail. By this means, keeping close to the sac, the hemorrhage is, as a rule, slight. Occasionally, where there has been inflammation, the adhesions are very firm, and the process is difficult and dangerous, since the vas deferens, or even the femoral veins, may be injured.

If an undescended testicle be encountered, it may be removed, since these are found to be without function. Not unfrequently a large mass of omentum is found in the sac, either free or adherent. We have met adherent omentum, especially in cases of strangulated hernia which had not been entirely reduced for a considerable time. In such cases we have noticed that the portion of omentum situated at the ring was constricted, and in some cases atrophied and closely adherent to the ring. In one case of ventral hernia there was an immense mass of omentum contained in, and adherent to, the sac. The portion situated at the ring was firmly adherent, and reduced to a fibrous mass, the protruding omentum being wholly nourished from its adhesion. It is worthy of consideration whether, if this protruding omentum be reduced, it may not be a leading factor in causing a return of the hernia.

In the case of the young man whom we shall show you, we removed a mass of omentum as large as the fist, and we have removed smaller masses at various times, and cannot see that the amputation of such portions of omentum complicates the operation. Care must be taken, however, to ligate the omentum very securely by one, or, if necessary, several ligatures. A friend told us of a case in which he had failed to do so. Serious hemorrhage had ensued. To secure the bleeding portion it was finally necessary to open the abdomen, and the omentum was found retracted to the level of the umbilicus.

Adhesions of gut, if present and firm, are serious. We have never met with any but slight adhesions which could be separated without danger and the gut returned. Should they be present, the removal of the portion of the sac to which the gut is adherent would be desirable, if possible, and the returning of this with the gut to the abdominal cavity.

The treatment of the sac itself is a point giving rise to much discussion. The plan of Macewen, to dissect it free from all adhesions, transfix it with a catgut suture, and draw it upward inside of the abdominal ring, but outside of the peritoneal cavity, has rendered, in the hands of its originator, excellent results. Whether this success is not as much due to the care with which he loosens up the peritoneum about the internal ring, and closes the ring itself, is in doubt among many operators.

After seeing Mr. Macewen's surgical methods, we must say that we have formed for them the very highest esteem, having seen very few surgeons so full of resource and sound reasoning. Other eminent surgeons, however, prefer to extirpate the sac entirely, ligating it as high up as possible. Whatever method be chosen, there are two important points in connection with the treatment of the sac: 1st, It should be freed thoroughly from the ring, and for a distance about its upper margin. 2d, Whether left as a convex mass above the internal ring, or cut off, no depression should be left above the ring. If the sack is excised, the peritoneum should be pulled downward as firmly as possible before being ligated, and the ligature should be placed as high up as possible, so that when the peritoneum retracts no depression may remain. Should a depression remain, there is a liability that it will constantly be deepened by the pressure of the gut upon it. For the ligation of the sac we believe catgut to be the best material.

The closure of the rings is all important. Shall we seek to close them by first intention or by granulation? The weight of opinion is certainly in favor of closing them by first intention, it being held that a cicatrix formed by first intention is firmer than one formed by granulation. The first operation which we performed for the radical cure of hernia was on May 14, 1885. This was before the publication of Macewen's cases or those of Lucas Championnière. In fact, up to this time we had noticed nothing with reference to the question of the closure of the rings.

The method of operation we adopted was to close the opening in the peritoneum with a catgut ligature, then unite the pillars of the ring with interrupted silk sutures, leaving one end long. A drainage-tube was inserted to just outside of the united pillars, and the superficial parts were united by interrupted sutures. An antiseptic dressing was applied, and continued for about one week. This was then removed and the wound allowed to suppurate. We argued that at the end of a week the peritoneal cavity would be effectually closed against all danger from suppuration, and that by allowing suppuration a larger cicatricial mass would be formed to resist a return of the hernia. As the sutures loosened they were drawn away. Perhaps this is not the best way. We certainly must defer to the experience of abler surgeons than ourselves in this matter. We do not hesitate, however, to claim that this is a good method. Certainly no case can be a severer test of a method than the one we show you here to day, and it is to illustrate this very point (viz., that cicatrices formed by suppuration are firm) that we have brought you this case.

The important point in the suture of the pillars is to approximate them thoroughly. To accomplish this we believe methods must be varied according to cases. In some we have found approximation easy; in others the rings have been tense and approximated with difficulty. We strongly suspect that in some cases these sutures cut through the tissues in which they are embedded, for we have found on tying sutures considerable resistance to the drawing of the pillars of the ring together, and it is a rule that tissues held tensely by sutures are cut by them.

All we can say is, that the suturing of the pillars by interrupted sutures, leaving one end long, dressing the wound antiseptically until the abdominal cavity has been thoroughly closed, and then allowing the wound to heal by granulation, pulling away the sutures as they became loosened, has secured for us satisfactory results.

Drainage we believe to be desirable. Though the wounds may heal without danger of retained secretions, the possibility of such secretion pushing its way toward the abdominal cavity, should such secretion be present, would indicate measures to avoid such a serious complication.

The superficial sutures should approximate accurately the tissues. The application of dressings is a matter which should receive most careful attention, since if poorly applied what might have given a good result may end in failure. Dressings should be ample, and firmly held by a spica bandage, in order to secure equable pressure upon the wound. By slightly flexing the leg, in applying the dressings and bandage, and, on putting the patient to bed, raising the head and laying the leg on a pillow, there is less tension on the sutures uniting the pillars, and the parts are kept at rest and firmly in apposition.

We believe iodoform and hygroscopic gauze to be the best dressing. The gauze is applied dry, and thoroughly impregnated with iodoform. This absorbs all secretions, and forms an admirable dressing. It is good practice to remove this in from three to four days, or sooner if saturated with secretions. It enables one to see whether the wound is in proper condition, and also permits the removal of the drainage-tube.

Too great haste to leave the bed is a grave error. We should prefer that a patient remain in bed a couple of weeks after the wound has healed, and then that he should get up very carefully and gradually, believing that thus a firm cicatrix is more sure.

The application of a truss after an operation we believe to be good practice. One case we show you has never worn a truss; the other has one on to-day. Many cases never require a truss; but if a good-sized soft truss be worn for a time, it can do no harm, and it is an added safeguard against the early yielding of the newly formed and soft cicatrix to the pressure of abdominal contents.

The prognosis in case of operation for radical cure of hernia we believe to be good. The danger of life in the hands of an operator competent to perform laparotomy is slight. It is certainly less than are the dangers incident to the hernia itself, especially if not thoroughly controlled by a truss. If an uncontrolled hernia be simply changed by operation to one easily controlled by a truss, it is worth the risk of operation.

What cases shall be operated? That all cases of strangulated hernia which cannot be reduced should be operated goes without saying. We believe that the radical cure should be applied to such cases, unless contraindicated by especial obstacles, such as the gangrenous condition of the intestines, the extremely exhausted state of the patient, etc.

Cases not strangulated, complicated by such general conditions as diabetes, tuberculosis, infirmity, and old age, should not be operated on. In infants, only strangulated, irreducible, and uncontrollable herniæ should be operated on, since those which can be retained by a truss tend to recovery. All uncontrollable cases in adults in good health should be operated on. Without it the future of the patient is a sad one indeed.

We believe that irreducible though unstrangulated hernia in adults should be operated on. Undoubtedly such cases frequently fill out their full lease of years, but many such cases result fatally. We believe a considerable number of such cases, if not a majority, to be due to protruding omentum held by adhesions. In an operation, as has been said, this can be amputated with little danger. A case of this sort living within reach of skilful surgical aid is not so grave as one lacking it; but we believe all such cases would run less risk from operation than from strangulation. In vigorous young men, having hernia held by a truss which causes pain, or retains a hernia unsatisfactorily, especially if these difficulties are increasing, we should favor operation.

We are not prepared to advocate the radical cure for hernia in all vigorous adults, but believe that the tendency of good surgery is to extend the limits of the operation. In concluding our paper we would present to you two cases to illustrate two unusually difficult and rare cases of radical cure. The first is of a boy, operated on December 9, 1886, at the age of two years and one month. The case was one of inguinal hernia, and could not be controlled after the most persistent efforts. The radical cure was performed by the method described. The case progressed without fever, and in all respects satisfactorily. He was kept in bed a considerable time, and then allowed to get up with a pad held over seat of wound by a cotton-flannel band about the pelves, with perineal band of the same material.

In August, 1887, eight months from time of operation, boy seemed perfectly cured, when he had a sharp fall; he was noticed to place his hand at once at seat of the rupture. Several days later a slight bulging was noticed. The boy was placed in bed. Tinct. iodini co., ♏ xv., was injected at seat of this bulging, and when the tenderness had subsided a water-pad truss was applied. The case at present time (June, 1888) seems to be perfectly cured; but the truss will be continued for some time to come, to guard against danger.

So far as we know, few if any cases so young have been successfully operated on. Fortunately the operation is rarely indicated, since most cases can be controlled by a truss and are thus cured.

The second case we present was operated on May 14, 1885. We have desisted thus long from publishing the case that the permanence of the cure might be indisputably established. The patient, aged twenty-five, had a congenital left inguinal hernia, the largest we have ever seen, hanging down one-third the length of the thigh. This could apparently be entirely reduced, and the scrotum could be invaginated, and the wide-open hand could be passed upward into the abdomen as far as the umbilicus. The opening was enormous. The hernial sac was opened, and though before operating we had apparently returned the intestines to the abdominal cavity, it was found that many feet of collapsed intestine remained in the sac, the intestinal contents alone having been returned. The wall of the sac was so much thickened as to obscure the presence of the intestines.

The operation for radical cure was performed essentially as described. The cavity formed by the enucleation of the sac was so large, and obliterated with such difficulty, that a small amount of secretion was retained, causing a small abscess, and a ligature cut short and retained caused a continuation of suppuration for a time. Aside from this the case progressed favorably in every respect. The patient has been doing the heaviest sort of work in a rolling-mill, has never worn a truss, and to-day is perfectly cured.

EPILEPSY ASSOCIATED WITH INSANITY.

By J. D. F. KINNIER, M.D.,

NEW YORK.

The subject of this communication is a woman, thirty-five years of age; family history somewhat obscure. As far as can be ascertained her history shows that she has been subject to epilepsy since she was fifteen years old, and has since continued to have epileptic convulsions at irregular periods. Owing to the dulling of her mental faculties she cannot give reliable information concerning the onset of her epileptic attacks. She speaks of the preparoxysmal stage as manifested by a queer feeling which pervades her entire system, and which she is unable to describe. For the past six months she has been under close observation, during which time she has had two series or batches of fits, the first of which occurred last December, and numbered thirty-five; the second batch occurred in March, 1888, and amounted to more than forty fits. The nocturnal fits are at times slight, or of the *petit-mal* variety; while the diurnal are very severe, frequently giving rise to most marked epileptic violence, during which she is very maniacal in action, and is restrained with difficulty. During her excitement she generally is quieted by a hypodermic injection of hyoscyamine varying from one-twentieth to one-thirtieth of a grain. When irritable, she manifests suicidal tendencies. She always knows when the fits are coming on, of which she gives evidence by becoming irritable, assaulting, and quarrelsome without the least cause. When spoken to at this time she breaks out into violent outbursts of passion, which are quite the opposite of her usual demeanor. When her epileptic irritability has passed away she is of a most pleasant and agreeable disposition, is quiet and orderly, and appreciates her surroundings. Preceding the onset of her fits she complains of symptoms which she says she cannot describe accurately. She says she feels a sense of fulness in her stomach and chest, that her head aches very much, and that she experiences a feeling of tightness about her throat, like to that of being choked or suffocated. At length a queer feeling comes over her and she remembers nothing more until after the fits have passed away, when she has repeatedly informed me she was after having a bad fit. Her face at the oncoming of a fit is expressive of anxiety, and there is a look of vacancy, gradually deepening into ferocity and anger, followed by severe epileptic violence and a series of convulsions. When spoken to just preceding the onset of a fit, her speech is decidedly defective, her answers are very slow, and she responds only to urgent questioning, showing that the brain is slow in receiving impressions. Her facial expression now changes and her countenance assumes a pale, livid hue, and she does not look at the one with whom she speaks. Her expression becomes now more angry, and her look of vacancy deepens; there is marked movement of the eyes from side to side, and questions addressed to her fail to elicit any response; but slight movement of her lips is noticed, showing that impressions are still made upon the brain, and that the conscious state is about to be replaced by unconsciousness. Her limbs being examined at this period were found to be in a somewhat rigid state, and her position characteristic of an approaching paroxysm. On March 15, 1888, a note was made, as follows: "She is becoming depressed and melancholy; she does not appreciate her surroundings, and is less industrious than formerly. She refuses to eat her food, perhaps owing to delusions of poisoning. The patient continued in this condition for the following day, toward the evening of which she complained of a queer feeling in her head, and said she felt as though the fits were coming on. At this time, three hours preceding the onset of her seizure, she appeared more dull and stupid; her brain seemed to receive impressions more slowly, and her articulation, previously fairly distinct, now became almost unintelligible. When spoken to she attempted to answer, but muttered in an incoherent manner, and it was impossible to understand what she said. At length the epileptic echo is heard, which is premonitory of the onset of a definite series of convulsions. A peculiarity in this case is the occurrence of the epileptic cry just preceding the fit, which, though commonly conspicuous in the insane epileptic, is yet wanting in all but a few cases which I have observed. Finally, a definite convulsion occurs, followed by a batch of seizures at intervals of a minute or so, the number of fits amounting to thirty or forty, and cease in about one hour and a half after the onset of the initial seizure."

The condition of the patient during her epileptic seizures is that of rigidity, which becomes evident shortly before the onset of her fits, and she continues more or less in this condition till after the final fit has occurred. After her fits she is dull and stupid, and suffers but little from epileptic exhaustion, as compared with many others of the patients, who are weakened very much after a few fits. This condition of rigidity is most marked in the upper extremities, the hands being tightly clinched, requiring considerable force to open them. The palms of the hands are at times lacerated, owing to the severe pressure of the fingers when the hands are tightly clinched; the tongue is frequently bitten during her fits, her head is thrown back, her arms hang by her side, her lower limbs are extended, and her body is opisthotonic. Spasmodic twitching of the mouth is observed at the beginning of inspiration, and lasts until the inspiratory act has passed away, when the mouth returns to its symmetrical shape. In this case the left corner of the mouth is drawn downward and outward, due to contraction of the platysma muscle, which becomes quite prominent during each spasm. With expiration the lips are puffed outward, and at the end of expiration there is a period of quiescence, following which the inspiratory movements begin again. During the prolonged intervals between her fits she enjoys apparent good health, but gives evidence of being delusional; her delusions, however, are of a fleeting nature. Rarely she has a single slight fit, just preceding and after which she is somewhat irritable, and following upon this state there are evident signs of dulling of her mental processes or slowness of apprehension.

The most remarkable phenomenon in her case is her epileptic mania, attacks of which, though constituting part of her epileptic paroxysms, also occur independent of her epileptic seizures. During her stage of epileptic violence she is very difficult of control, attempting to assault any one who may chance to come near her. I have carefully observed this case in order that I might ascertain the relation, if any, of the aura to her epileptic seizures, and I am satisfied of the existence of some relation between the apparent movements of the patient and objects about her, and the direction in which the head is turned at the commencement of her fits. It is very difficult to obtain from the patient information as to the side on which the spasm begins, or is most marked, at the onset of her epileptic seizures. But there is every reason to believe that the apparent movement or initial rotation is generally in the same direction, or, in other words, the patient feels herself to turn in the same direction as her eyes and head appear to be drawn at the commencing spasm of the convulsion. I am inclined to think the attacks begin on the right side, as she feels herself drawn from left to right side; that she is giddy or dizzy in her head, and that she has noises in her ears. When in a fit she appears to be most convulsed on the right side. The aura or giddiness in the majority of the cases examined appears to proceed from right to left, as the patients complain of feeling themselves turning in this direction, and that external objects seem to rotate in a similar manner as they themselves. In other cases the fits began on the left side of the body, and the head was turned to the left at the beginning of the spasm. Several of the patients inform me that they can tell when a fit is about to come on because they feel the left corner of their mouth to twitch, that their heads turn to the left, and the left arm is drawn up. Having observed these patients while in fits I have no reason to doubt the accuracy of their statements. Another patient has repeatedly informed me that she seems to go round to the right, as well as everything about her, and that this condition is preceded by a feeling of sickness which begins in her stomach and goes to her head. Her fits begin with rotation of her head to the right, and various colors appear before her eyes. I have observed several cases in which the fits began by turning of the head to the left and drawing up of the left arm, others in which the head turns to the right with a slow and gradual motion, the patient falling on the side toward which the head is turned.

Of the many cases under observation there is every reason to believe, so far as the statements of the patients can be relied upon, that there is an apparent rotation of patients and their surroundings in like direction at the beginning of the initial clonic spasm. I have conversed with some patients who assured me that they and their surroundings seem to go to the right, while the attendants in charge of the ward, who are very observing, state that at the onset of a fit the patients' heads turn to the left, that the left arm is drawn up and the left side is convulsed more than the right. This is probably explained by the fact that a bilateral convulsion occurs, probably beginning on the right and then extending to the left side, where the convulsion becomes most marked. Of course there is always a certain allowance to be made for the remarks of this class of patients, but in case of doubt it is always well to have the patient, when free from fits, illustrate which way she would turn in case giddiness was coming on. I think I have derived sufficient information from the patients, attendants in charge, and from personal observation to justify me in asserting that at the onset of an epileptic seizure the patient appears to turn in a definite direction, as also her surroundings, and that the primary tonic spasm begins in the corner of the mouth or in the hand, on the side toward which the apparent movement of the patient and surrounding objects takes place. Pressure on the tragus of the right ear in one patient, who suffered from purulent otitis due to scarlet fever when a child, produced giddiness with a tendency to fall. Several years after the commencement of her ear trouble she became subject to epilepsy, which I think can be attributed to her ear disease as the causal factor, as I believe disease of the ear to give rise to epilepsy, especially when the aural disease follows upon attacks of scarlet fever.

In these cases the epilepsy is probably produced by some peculiar action of the poison of scarlet fever on the nervous system, or by extension of the throat affection to the tympanum, which is followed by inflammation of the middle ear. It would appear, then, that some relation exists between epilepsy and ear disease, for we occasionally meet cases where ear disease followed by epilepsy occurs after scarlet fever, and look upon the ear disease as a connecting link between the fever and epilepsy. But this condition is not always found to exist, as we meet with cases where epilepsy and ear disease result from scarlet fever independent of each other. Many of the cases complain of a ringing or drumming in their ears just preceding the fits; in these cases aural examination revealed nothing abnormal.

The case to which the above remarks chiefly apply was selected as the most suitable, because her fits always occur in batches of thirty-five or forty, lasting about an hour and a half, after which the fits will not recur for three or four months, and seldom has she a fit during this interval. In studying a case of epilepsy much difficulty will be met with in arriving at a definite diagnosis of the so-called slight fits, the outward physical symptoms of which are at times so slight as to be passed over unnoticed, especially when epilepsy is associated with insanity, in which case they may be overlooked, as they are occasionally reduced to outbursts of passion or attacks of irritability. The matter of treatment has not yet been thoroughly tested, and hence I cannot vouch for the efficacy of the bromides, or the nitrate of sodium, or other drugs which are lauded so much in the treatment of epilepsy.

TWO CASES OF INTRANASAL DISEASE.[1]

By ALFRED HINDE, M.D.,

SURGEON EYE AND EAR DEPARTMENT CENTRAL DISPENSARY; OPHTHALMOLOGIST TO NEUROLOGICAL CLINIC, RUSH MEDICAL COLLEGE, CHICAGO, ILL.

I. Rhinolithiasis.—G. R. K——, a bright and lovely little girl, in her fifth year, was referred to me by Professor H. M. Lyman and Dr. W. K. Harrison, on account of nasal and aural disease, and she was first seen by me March 27th last. The following history was given: When the patient was six weeks of age a suppurating inflammation with discharge from the ears occurred. The latter ceased in a short time, however, under appropriate treatment. Since then, and after "catching cold," and preceded by earache, the aural discharge has many times returned.

About one year ago an increased nasal discharge appeared, and has since then still further increased, and has continued until the present time. Nasal syringing with boric-acid solution has been resorted to with little result, other than preventing a marked fetor which the discharge otherwise possessed. The child's mother, about six weeks ago, first noticed, when douching the nose, a white object in the left naris, and this has been seen daily until the present time.

Status præsens: From the appearance of the membranæ tympani—opaque, thickened, irregular in surface, with the usual landmarks partially obliterated—together with the fact that bone conduction in all positions is more distinctly heard than aërial vibrations, and with marked deafness for the watch, middle-ear disease is diagnosed.

The tonsils are slightly enlarged, and the posterior pharyngeal wall is covered with mucus, and dotted with enlarged follicles—the latter increasing in number upward. From the latter fact, together with the mouth-breathing, deafness, and slightly nasal voice, pharyngeal glandular tissue is suspected.

After carefully conducted, yet thorough nasal douching—the same removing a large amount of secretion, especially from the left side—anterior rhinoscopy reveals a reddened, swollen, mucous membrane, and in the left naris a yellowish-white object, plainly visible, and about one inch back of the anterior opening. With the probe the object is movable, and its surface slippery and soft, and without grating sensation. It occupies the inferior meatus, and extends upward between the inferior turbinate body and the septum, and appears to be about one inch from above down, though its peripheral portions are not definable on account of the swelling of the surrounding mucous membrane.

Its appearance suggested inspissated secretion, and the probe seemed to confirm this idea, yet with angular aural forceps repeated efforts to grasp the body resulted only in slight hemorrhage and failure—the object slid from between the jaws of the instrument at each attempt, a little dried mucus alone being extracted and no grating sensation observable. Daily nasal douching with warm sodium bicarbonate solution was advised, and office visits requested on alternate days, and after eight days the yellowish appearance of the body had given place to a dull white, roughened or slightly worm-eaten look; and to the probe an unmistakable grating on friction was evident, and the attendants could hear a click on striking the body with the end of the instrument. Its size smaller; its mobility increased; its calcareous nature unmistakable; it was now known to be a rhinolith, and yet, on account of the disparity in size between the anterior nasal opening and the stone, anterior extraction *in toto*, or by crushing, was impossible, for the calculus could not be grasped with any forceps—it invariably slipping backward on each attempt. Two days later the efforts were repeated with like results, and in the hope of finding a surface of the stone that forceps could be made to grasp, an attempt at rotation of the body was readily successful, but just as the act was accomplished the calculus disappeared from view—it had slipped further back into the posterior portion of the nasal cavity, or into the naso-pharynx. With the probe the denuded bone-grate was elicited at a greater depth, and further attempts at extraction were thought inadvisable without professional assistance, and an appointment with Dr. Harrison three days later was decided upon.

At this time no difficulty at posterior extraction was contemplated, and expecting that but momentary suffering would result, an anæsthetic was not given. The little patient was held in the doctor's lap, the feet held between his legs, and the shoulders and arms were covered and restrained with rubber sheeting. The mouth-gag was introduced on the right side, and it, and the head, were steadied by an assistant. Seated in front of the little patient I passed a large, well-curved Eustachian catheter along the opposite (right) nostril, and into the naso-pharynx, so that its tip extended to the lower border of the velum palati. The left index-finger was next passed into the throat until its tip touched the end of the catheter already *in situ*, and thus hugging the instrument the finger passed easily and quickly behind the velum; the only obstruction found was a large amount of pharyngeal glandular tissue in the vault, as already suspected. The finger-tip now closing the left posterior nasal opening, a good-sized cannula, with roughened end, and the latter protected with tightly wound absorbent cotton, was passed, first, along the left inferior and then along the middle meatus, with the intention of pushing backward the rhinolith through the posterior opening, the finger then guiding it into the mouth, the patient's head tipped forward at the same time, thus avoiding the principal risk, viz., that of the foreign body falling into the trachea. The chagrin was great; no calculus was found! The inferior meatus was enlarged in its posterior half; the middle meatus was empty! Yet, before we commenced the procedure the dead-bone grate was elicited with the probe in the naris at one and a half inch from the anterior nasal opening, and found by both of us. Afterward it was again found to be still present, proving that denuded bone was actually the cause. Previous to the withdrawal of the finger, the very friable pharyngeal tonsil was scraped off with the finger-nail, a fair amount of venous hemorrhage resulting. With the exception of the temporary apnœa, as shown by the facial cyanosis during the presence of the finger in the naso pharynx, the little patient did not appear to suffer much, and the conciousness of the little one was retained, so that in case the calculus had eluded the finger and dropped into the larynx, the reflex cough resulting would have expelled it.

---

[1] Read before a meeting of the Chicago Pathological Society, June 11, 1888.

From the foregoing it will be seen that, at the time of the sudden disappearance of the rhinolith on rotating it three days previously, it had then most probably passed into or beyond the posterior nasal opening, and had at that time, or subsequently, been swallowed. My error consisted in mistaking the still-present dead-bone grating as dependent upon the presence of the calculus, whereas, actually denuded bone had resulted from the pressure of the foreign body, and the hemorrhage present in the early examinations was now explained.

The procedure was, however, fortunately justifiable on account of the presence of hypertrophied glandular tissue in the pharynx, and its destruction. The general health of the little sufferer, which had been greatly impaired since the onset of the catarrhal symptoms one year previously, immediately commenced to improve. The nasal respiration was again restored, the mouth-breathing ceased, the nasal twang vanished, the rhinorrhœa rapidly diminished, and the exuberant cheerfulness of the child again returned.

The English literature of rhinolithiasis, as far as my brief search has gone, is very limited. It is barely mentioned in some of the surgical text-books, and is entirely overlooked in many of the special throat and nose treatises. From the latter fact the infrequency of these cases may be inferred.

According to Morell Mackenzie,[1] Demarquay, a French observer, collected fifteen cases of the disease, and was one of the earliest writers on this subject. From him it is learned that the earliest reference to these concretions is in a work by Matthias de Gardi, published in 1502, wherein a case is vaguely mentioned. Bartholin (1654) observed two cases. Claude (1685), Kern (1700), Reidlinus (1706) recorded single cases, and Wepfer (1727) described two instances. Ruysch comes next (1733) with a case, and other cases were those by Saviales (1814), Gräfe (1828), Thouret (1829), Axmann (1829), Brodie (1844), Demarquay (1845), Cook (1847), Köstlin (1854), Rouyer (1857), W. N. Browne (1859), Verneuil (1859), West (1872), Erichsen (1872) mentions two cases, Roe (1880), Hering (1881), Nourse (1883), and Mackenzie gives the histories of two cases occurring in his own practice (1876, 1882).

In 1884 J. Bettman[2] read a paper before the Chicago Medical Society, and reported a case. R. E. Beach,[3] in 1885, recorded two cases.

Many of the following main facts are taken from Mackenzie and Bettman. Demarquay, in 1845, named this condition "rhinolithiasis." Stoerk had seen but one case up to 1880.

The nucleus of a rhinolith is usually a foreign body inserted into the nostril during childhood. In Mackenzie's cases, and one of Bartholin's, no nucleus was found. In Hering's a button formed the nucleus. In one of Bartholin's cases, in Bettman's, and in one of Beach's cases the nucleus was a cherry-stone. In Beach's second case a small seed was found in the centre of the concretion. Nasal secretion, dried or otherwise, may form the centre, as in Browne's and Thouret's cases.

In Bettman's case the calculus was supposed to have been in the nose for forty years, and Jacquemart had a case of over twenty years' standing. Beach's cases were both children of four and twelve years, and the condition had existed for eight and eighteen months respectively.

In size they vary from a lentil (Rouyer) to a small plum (Voltolini). In Browne's case the stone measured in length $1\frac{3}{4}$ inches; breadth, 1 inch; thickness, $\frac{1}{2}$ inch, and weighed three drachms and thirty-three grains. The smaller stones may be extracted anteriorly without crushing; but the larger ones must either be cut, crushed, or removed posteriorly, as in Hering's, Mackenzie's, Bettman's, and the accompanying case.

Chemically the rhinoliths consist mainly of carbonate and phosphate of lime, and are usually coated with a "soft, pultaceous, fetid material composed of epithelial débris, pus, and cholesterine."

Fetid rhinorrhœa is usually present, with or without epistaxis, and polypi and denuded bone may be associated conditions in this as in middle-ear disease.

The stones are rarely multiple, as in Axmann's, Blandin's, and one of Mackenzie's cases.

The diagnosis in many cases, especially where the calculus is situated posteriorly, is by no means easy, and these cases have been mistaken for osteoma, for necrosis with sequestrum, as in Bettman's and one of Beach's cases; for cancer, on account of the "fungous bleeding appearance of the mucous membrane" (Jacquemin). Jacquemart's case was diagnosed by himself and ten consultants as osteosarcoma.

The usual seat of the stone is in the posterior portion of the inferior meatus. In one of Mackenzie's cases, however, the stone was found in the middle meatus, and in his other case it extended "from the level of the inferior turbinated body to the roof of the nose."

Surgical removal is necessary, and with small stones anterior extraction *in toto* with dressing forceps is resorted to. Where too large for such removal, and yet can be grasped with a lithotrite, they are crushed and the débris removed with the douche. In those cases that cannot be removed by these methods, posterior extraction through the naso-pharynx and mouth, as already detailed, must be resorted to. On removal rapid subsidence of symptoms results.

II. PRIMARY INTRANASAL CARCINOMA.[1]—W. S——, aged twenty-nine, a vigorous-looking, well-nourished American, by trade a trunk-maker; first noticed, five years ago, a stenosis of the right nostril. Professional advice was then sought, and, in the doctor's own words, "a simple amorphous polypoid tumor, with not more bleeding than is frequently seen," was removed. "One year later," the doctor writes, "I removed a similar, though more vascular tumor, with considerable hemorrhage. Macroscopically benign in character. I did not have my suspicions aroused. Six months later he presented himself with a tumor entirely filling the orifice, very vascular, and breaking down easily under the forceps. The pieces I removed were very small, and none were saved. I used a curette, and then the cautery. He was instructed to return for treatment. I expected then to be able to get a portion for microscopical examination, but he failed to return, and I began to think, after all, it was benign, and that the cautery had cured him. He is marked cured—so statistics are made." The patient afterward passed on to the care of another specialist, and was operated on three times during the year 1886. From this practitioner, however, no details are obtainable, and he barely remembers having had such a case. In July, 1887, he became the patient of still another physician, and he writes as follows: "Mr. S—— has been under my treatment for some time. I removed the growths from nose and tear-sac, but they soon returned. The growth, in my opinion, is a fibro-sarcoma, and certainly demands a radical operation."

This patient was first seen by me on January 17th last, and the following are the details of his condition at that time: There was a tumor just below the right internal canthus, and on the right side of the nose, about the size of a hazel-nut—elastic on palpation and fixed deeply.

[2] Journal of the American Medical Association, September 6, 1884.

[3] THE MEDICAL RECORD, July 11, 1885.

[1] Patient exhibited, and microscopic sections of the tumor shown at the meeting.

There was complete stenosis of the right nostril, and the latter cavity was completely filled—with the exception of a small portion anteriorly near the septum—with a gelatinous-looking vascular growth, bleeding freely on the slightest touch. On posterior rhinoscopy the tumor was seen extending through the posterior nasal opening, and the adjacent roof of the pharynx was reddened and swollen. Its appearance was the same as already described—the blood-vessels could be distinctly traced near and upon its surface. The right Eustachian orifice was not involved, and the hearing was alike and normal on both sides. Ophthalmoscopically the retinal vessels were seen to be unduly tortuous, yet otherwise the fundus of each eye was normal and the vision was good. The patient was the picture of health, and said that during the recent winter he had actually gained in weight. In the hot weather, as is the rule, however, he says he loses flesh. He came for advice and operation, and from his past experience well knew that only radical methods would avail in his case. With such a history and present condition a malignant tumor could alone be diagnosed, yet its exact nature was unknown. The expediency of further operation was questionable after such persistent recurrence, with an area of growth so extensive, and with more than probability that its seat of origin involved the ethmoidal cells at least, and possibly the antrum and sphenoidal cavities. From the tortuosity of the retinal vessels orbital involvement was thought of as possibly commencing, and might we not have an intracranial extension as readily as the one present on the facial surface, though not yet evident by cerebral symptoms? Mackenzie,[1] referring to such extension, writes: "It is remarkable, however, that the cranium may be perforated or eroded over a considerable area by the tumor without any cerebral disturbance being produced," and refers to several such cases published in a thesis by Petit (Paris, 1881, pp. 25, 26, 32, and 37).

With these considerations, and incredulous as to permanent benefit, even from the most thorough yet necessarily incomplete extirpation, and remembering the possible risk of injury from such procedures to the intracranial contents, operation was refused. He still persisted, however, and was referred to Dr. Charles T. Parkes, who subsequently removed the facial growth, which, on microscopical examination, consisted of alveoli of glandular epithelial cells, embedded in a matrix of connective and myxomatous tissue in different portions—the later growing most probably from the mucous membrane of the lachrymal apparatus. Still later, Dr. Parkes removed the intranasal growth by Langenbeck's method, which is briefly as follows:

A cutaneous incision was made in the median line from the base of the nose to the osseous extremity of the nasal bone; then bending the cut obliquely outward and downward, and passing through the cartilage of the tip it was continued, to the junction of the nose with the cheek. This angular flap was now reflected upon the cheek. With bone-forceps the nasal bone, in the median line, was cut through from tip to base; then a parallel osseous incision in the outer portion of the nasal cavity, through the nasal process of the superior maxilla, was made. These two incisions were joined by still a third, at right angles to the other two, and carried through the base of the nose. The cut bone was now turned out of the way, yet still attached by threads to the surrounding tissues. The cavity, then in plain view, was seen to be filled with the growth, and the latter was readily removed with finger-tip and curette—so friable was it—and the hemorrhage was quite profuse. The growth was found to extend into the anterior ethmoidal cells, but the other cavities were not explored. After freeing as far as possible the nasal fossa, the wound was closed, and the patient made a good recovery; his weight, however, two weeks later, was found to be ten pounds lighter, showing that an operation of this character is worthy of careful consideration.

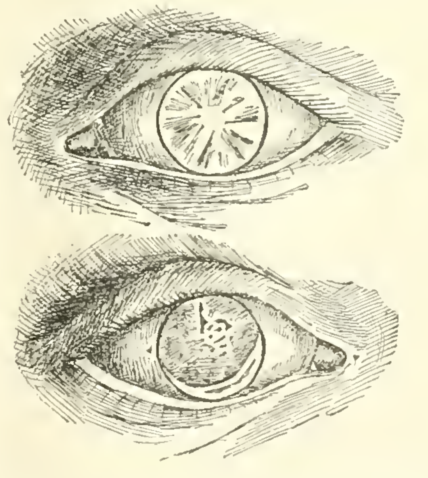
Six weeks following the operation the patient was again seen, and rhinoscopic examination showed that the tumor was again budding out from several points of the cavity, and in all particulars the same as before described. After an interval of three months from the time of operation the nasal stenosis was again complete, and the condition of the patient the same as when first seen—he having gained again eight pounds of the ten lost as the result of the operation. The facial growth was again about the size of a hazel-nut. The intraocular circulation was now normal, however, the vascular tortuosity seen previous to the operation having disappeared.

Microscopic examination of the intranasal growth showed the same alveoli of epithelial cells occurring in a large amount of vascular myxomatous tissue. The knowledge of malignant nasal polypi dates back to the time of Hippocrates, and those interested may be referred to Mackenzie's[1] historical sketch of these growths.

A CASE OF CONGENITAL ABSENCE OF THE IRIS, WITH CATARACT, DISLOCATION OF ONE LENS, NYSTAGMUS, AND STRABISMUS.

By WARD A. HOLDEN, A.M., M.D.,
CINCINNATI, O.

INSTANCES of aniridia are rare, but the following case is especially remarkable on account of the number of complications it presented. M. R——, a boy aged ten, with light hair and a fair skin, was seen in May, 1888. The irides were wanting in both eyes, and the lenses were hazy, with the right one dislocated. There was also a lateral nystagmus, and besides this, a slight convergent strabismus, which previously had been well marked When the eyes were observed with ordinary illumination, all behind the cornea had a hazy, bluish-black appearance, like the heavily pigmented iris of the negro, where neither detail nor margin can be distinguished, and it was impossible to tell whether an iris was present or not. Under the oblique illumination the opacities near the centre of the lenses were seen, but outside these was the same indistinctness. With the ophthalmoscopic mirror alone could the true condition, as shown in the sketches, be determined. The only vestige of iris to be seen in either eye was a pigmented line at the sclero-corneal junction. The right lens was dislocated upward and outward, its margin was slightly irregular, and scattered through it were diffuse nebulæ and a few punctate opacities. The left lens was in position, but had spiculæ of opacity running from the periphery toward the nucleus.



This eye illustrated the magnifying power of the cornea and aqueous humor, which is not often thought of in examining the iris or lens. For while the lens is small enough to slip easily through a flap in the cornea in this case. at a few inches distance no part of the margin of the lens could be seen through the cornea without moving the head to one side.

---

[1] Diseases of the Throat and Nose, vol. ii., p. 499, 1884, under "Fibrous Polypi of the Naso-pharynx."

[1] Diseases of the Throat and Nose, pp. 385, 386. 1884.

It was impossible to get a distinct view of the right fundus, but in the left eye the fundus could be seen through the centre of the lens, and appeared normal in every respect. Vision was about $\frac{10}{200}$ in each eye, and the patient thinks that it is as good now as it has ever been. Lenses of 3 D — improved it slightly. The color-sense is normal. The sight is much better in the evening and in cloudy weather than in the sun, where he pinches the eyelids closely together to keep out the light. The patient's brother and sisters have perfect eyes, and the father and mother never complained of any ocular trouble, and wore glasses only for presbyopia. There is no history of any deformity in the grandparents, or in collateral branches of the family as far as known.

TREATMENT OF INSOLATION.

By R. ELLIS, M.D.,

NEW YORK.

During the few days of intense heat in June, as ambulance surgeon of a city hospital I was called upon to treat five severe cases of sunstroke. As the cases were very severe and the results good, I should like to present a résumé of each case.

Case I.—Young man, aged twenty-two, German, butcher by occupation. I found him in a dark hall, apparently moribund. He was as hot and dry as a cinder; pulse, 160; temperature, 108° F.; respirations weak and sighing, and with involuntary evacuations. He was immediately stripped, ice-water applied by sprinkler, and tr. digitalis, ♏ x., and antipyrine, gr. xx., given hypodermically. Twenty minutes later, the air being very close in the hall, the patient was covered with a blanket and placed in the ambulance. On the way to the hospital three stops were made for water (some ice still remaining). After reaching the hospital the ice water was continued five hours with intermissions—the temperature falling to 99.3° F., but rising again to 105°, which was easily reduced to 101°. The patient opened his eyes two hours after reaching the hospital, and was rational seven or eight hours after. For two successive days his temperature rose to 105° F., but was reduced by quinine and cold sponging. Discharged on the fourth day, with no apparent sequelæ.

Case II.—Baker by occupation; had been lying on the sidewalk two hours uncared for. Temperature, 107° F.; pulse almost imperceptible, pale face, hot and dry skin, involuntary evacuations. He was stripped to the waist, ice-water was used immediately, and tr. digitalis, ♏ x., and antipyrine, gr. xx., given hypodermically. After working with him forty minutes, his pulse improving somewhat, he was brought to the hospital, reaching there about 8 P.M.; it was 2 A.M. before the physicians considered it safe to leave him. His temperature was reduced to 100° F. within two hours after admission, but unless the cold treatment was kept up the temperature would quickly rise to 103–4°. The patient had slight rise of temperature for several days, but left the hospital in a week, seemingly perfectly well.

Case III.—An Italian dock-laborer; had been without treatment two hours. Pulse, 170; temperature, 108.6° F.; involuntary evacuations and vomiting. Patient was stripped, and ice-water used immediately. The pulse was so weak and general appearances so bad that he was not placed in the ambulance for one hour. Hypodermics of tr. digitalis, ♏ x., and antipyrine, gr. xx., were given. On the way to the hospital, stops were made for water. On reaching the hospital, temperature was 100° F. The patient was put in bed, but, the temperature soon after rising, cold was used at intervals from 7 P.M. to 1 A.M., when the physicians considered it safe to leave him.

The next day his temperature was 102° F.; patient was dull and sleepy, but the second day after he was brighter, and left the hospital on the third day perfectly well.

Case IV.—An iron-moulder, who complained of feeling sick a few minutes before he fell. Patient was stripped, laid on boards, and ice-water applied till the temperature fell a little and pulse grew stronger (temperature, 107°F.; pulse, 164). At the hospital the patient was cared for as were the others, the thermometer being kept in the rectum and consulted every few minutes.

A singular feature of this case was the rapidly changing expressions which would sweep over his face.

As soon as he became half-conscious, he made things lively by yelling "murder" repeatedly and by trying to bite the attendants. By slapping his back and calling him "Tom, old fellow!" he would laugh quite pleasantly for a few seconds, when again there would sweep over his face a look of fear and anger, and he would renew his cries of "murder." Finally, morphine, gr. $\frac{1}{6}$, was given hypodermically and the patient gave no more trouble.

Case V.—A man, brought to the hospital by an outside ambulance. Patient was stripped immediately, and ice-water applied. Surface-temperature felt normal, but rectal temperature was 110°F. This being the limit of the thermometer, his exact temperature was not found, but the finger in the rectum showed the man to be as hot as a furnace.

He was immediately carried to the bath-room and placed in ice-water. Being a stout, full-blooded man, he was bled, the venous blood being very dark and coagulating almost as soon as it oozed out. Hypodermics of tr. digitalis and antipyrine were also given. Notwithstanding heroic treatment the temperature remained above 110°F. for over thirty minutes.

The temperature fell to 108° F. in one hour More tr. digitalis and antipyrine were given, and cold treatment kept up till, in about two and one-half hours, the temperature was 102°F. Then the cold-water treatment was stopped and blankets were made ready in case the temperature fell below normal.

Notwithstanding the use of blankets soaked in hot water the temperature fell to 96°F., but soon rose to normal. Soon after the temperature became normal, the patient slowly opened his eyes, raised his hands above his head, and soon after died, his pulse and respiration having been weak and feeble from his entrance till his death.

The first four cases developed tonic muscular spasms so well marked that they could be lifted by the head and heels without the body relaxing. In these cases, especially in No. 3, the jaws were held open by a mouth-gag and the lips kept apart by the fingers, to prevent them from biting their tongues and lips and to enable them to breathe more easily.

I have seen a case of insolation where, after the patient was recovering and in the tetanoid stage, an "ice-bag to the head" was ordered and the patient died before morning, his lips being tightly pressed together and swollen to twice their normal thickness. From the experience of several physicians it seems to be agreed that, in the treatment of insolation:

1. Every ambulance should carry ice, a sprinkler, and pail, and the patient should be treated on the spot till the ambulance surgeon feels it safe to move him.

2. Every patient should if possible be *stripped*, a sheet or blanket covering him when carried to and from the ambulance.

3. The thermometer should be placed in the rectum and kept there during the entire treatment, the advantage of knowing just the temperature at any minute being vastly more useful than the slight reduction gained by rectal enemas of ice-water.

4. If the heart is weak, and especially if any heart depressant has been given, as digitalis, quinine, or antipyrine, the patient should be kept as quiet as possible, and under no circumstances should his head or body be raised.

5. If the patient has a very high temperature (108° to 110°F.), care should be taken not to reduce it below 102°

to 103° too hurriedly, as the tendency in some cases is to fall below normal.

6. If a spasmodic stage occurs, and the patient has locked jaws and tightly pressed lips, the mouth-gag should be inserted, and the lips held open if necessary.
7. The ice-bag to the head is useless, save in subsequent treatment.
8. The judgment of the physician must decide when to "bleed," to "rub," to give stimulants, to stop "cold" treatment, to remove to bed.
9. The thermometer in the rectum is the basis for all treatment.

THE THERAPEUTICAL VALUE OF MINERAL WATERS IN THE DISEASES OF CHILDHOOD.

By ISABEL LOWRY, M.D. Paris,

SAN FRANCISCO, CAL.

The American physician who spends any considerable time in foreign schools and hospitals must often be struck by the great efficacy which is attributed to a course of bathing or of drinking the waters at the numerous springs of Europe, as well as by the thorough scientific classification of the different waters and the exactitude and discrimination with which they are prescribed in given maladies and diatheses. Particularly is this the case in France, a country which is probably richer in bathing resorts than any other on the continent. In the children's hospitals this is especially true, and in the wards of such authorities in pediatrics as the late Professor Parrott, of the Enfants Assistés, or at the crowded *conférences* and clinics of that master of infantile therapeutics, Dr. Jules Simon, of the Enfants Malades, the student can hardly pass a day without hearing mineral waters prescribed, either as active treatment or as an aid to convalescence.

The secret of the brilliant results experienced in this line of treatment lies in two things—in the careful analysis of the waters and of their effects, and in the exact study of each case before recommending a spring.

A rough diagnosis of the disease is not enough. Temperament must be studied, diathesis decided upon, surroundings, accommodations, temperature, and cuisine considered by the sagacious physician. If personal inspection can be added to these it leaves almost nothing to be desired. It would not be too much to demand that each physician be familiar, at least, with the springs of his own State. That these questions have been reduced to scientific principles by French and German *savants* is very evident, and a new arrival in their clinics is more apt to be bewildered than edified by the discussion as to the relative therapeutic merits of Bourbonne-les-Bains, Schwalbach, Aix-la-Chapelle, Vichy, Forges, Salins, Mont Dore, and an innumerable host of other springs. The mineral-water establishments of France are thought worthy of the appointment of a government inspector (le médecin-inspecteur des établissements d'eaux minérales naturelles), and the government in 1880 and 1884 gave prizes to those physicians who produced the most noteworthy works on mineral waters.[1]

Dr. Jules Simon, the authority on infantile therapeutics, himself made a tour of all the stations d'eaux in France, personally examining their effects, and embodying his experiences in a series of brilliant *conférences* which have since been published.[2] A similar plan in regard to America is less feasible when areas are considered, but even a partial analysis and comparison of the principal waters would throw much light upon this question, and therapeutics may gain many new and powerful agents through the careful collection and publication of the experiences of educated physicians.

American literature on the subject of balneology is conspicuously deficient, and, as Dr. T. M. Coan[3] has shown, compares most unfavorably with the full and exhaustive treatises of such men as Trousseau, Braun, Simon, Leichtenstein, and Rotureau; but this hiatus is easily understood in a new country like America, which was undiscovered when many of the famous springs of Europe were at the summit of their popularity. This gap will be filled in time, and if physicians resident at springs would produce monographs comparable with those of foreign countries,[1] the American physician need no longer seek a European resort for his wealthy patients. We certainly possess as many and as valuable springs as Europe. Our waters equal the foreign, but, with the exception of Saratoga and a few others, none have been as exactly tested nor as accurately analyzed.

Let us see what mineral waters are of therapeutic value in the diseases of childhood, and how they may be advantageously employed. The leading springs may be put under the following headings: 1. Saline (alkaline, muriated, sulphated). 2. Sulphurous. 3. Gaseous or carbonated. 4. Ferruginous (carbonated, sulphated). 5. Arsenical, which, strictly speaking, should be distributed under the preceding categories, there being few waters in which arsenic is the leading constituent.

I. Saline.—These waters hold in solution different salines (generally sulphates, carbonates, or chlorides, in combination with soda, potassium, lime, or magnesia) which impart to them corresponding properties. Occasionally a saline water, especially a saline muriated, contains iodine and bromine, or iodide of potassium, and such are valuable tonics in scrofula. Sea-water properly enters this class. But in considering mineral waters it must be remembered that their effects are not entirely due to their mineral constituents. Much seems to depend upon the organic and extractive materials derived from the earth and plants, upon the temperature, and upon the gaseous elements.

These waters are generally aperient. Epsom, Carlsbad, Seltzer, Apollinaris, Baden, Ems, Bourbonne, Salins, Salzbrunn, in the old world; Hathorn or Ballston, Greenbrier, Capon, California Seltzer, Congress, Cal.; Saratoga Vichy (alkaline saline, like the European Vichy), and Bethesda, in America, are of this class.

When are saline waters indicated? They are strongly called for as alteratives in the scrofulous diathesis (Simon,[2] Keating[3]) and with anæmic or lymphatic children who cannot endure sea-bathing. They are a precious resource in those cases where the presence of nervous disorders, cerebral irritability, rheumatism, cardiac, cutaneous, renal, ocular, and auricular diseases, or susceptible respiratory mucous membrane categorically forbid sea-baths. In torpid scrofula the stronger saline waters are best. The Greenbrier Spring is deservedly in repute in these cases, as well as the Deep Rock Spring at Oswego.

The best mode of employing them is as hot baths. Simon, to whose personal instruction in, and writings upon, this subject I am much indebted, lays more stress upon their use in baths than on their ingestion. When considerable carbonic acid gas and oxygen are present he allows the waters as an aid to digestion, but warns his readers not to trust too implicitly in this internal medication, which possesses the disagreeable disadvantage of sometimes causing, instead of calming, gastric troubles. In diathesic scrofula Salins and Kreuznach work many cures. In searching through the analyses of American springs none seems to me to so nearly approach the famous French eaux as St. Catherine's, Ontario, a peculiarly concentrated water, containing, like the Kreuznach, large percentages of sodium, magnesia, and calcium chlorides, and small percentages of iodine and iron. St. Catherine's has proven peculiarly successful in scrofula, as baths. Internally it must be given much diluted with ordinary water. Spring Lake Well, Mich., also approaches in composition the Kreuznach water.

[3] Clinical Lecture on the Therapeutics of Natural Mineral Waters, etc., Philadelphia Medical Times, July, 1886.

Some scrofulas, however, prove entirely rebellious to saline baths, and these should try sulphuro-saline waters, as those at Massena, N. Y., which are to be recommended in the scrofulous dermatoses and chronic ophthalmias. These sulphuro-saline waters can be given internally, but with prudence, beginning with minimum doses and increasing *à tâtons*.

For that obesity, accompanied by atony and feebleness, which is so often present in scrofulous children, one of the more purgative saline springs is to be recommended, and in the anæmia of scrofula a water like that of the Hathorn Spring is called for (Coan).[1] A distinction must be made between the scrofulous form of anæmia and that resulting from convalescence or too rapid growth. The latter demands a ferruginous spring, and although I have as yet found no report of its mode of action, it seems, from the analysis given, that the Warm Spring of Madison Co., N. C. (saline-chalybeate), would meet the requirements. When chlorosis accompanies anæmia, sea-bathing is the best form of hydrotherapy. In scrofulous phthisis, as well as "erethic" or irritable scrofula, a water corresponding to La Bourboule is desirable in conjunction with ol. morrhua (Simon).

In chronic synovitis, articular inflammations, etc., after the classic treatment has put the inflammation upon the road to resolution, the cure may be consummated by a season at a saline or sulphur bath, accompanied by a course of massage.

Rachitis.—Here sea-bathing is the most successful form of hydrotherapy; but if this be counter-indicated prescribe saline or sulphuro-saline baths, although much less effective results are to be anticipated.

Hot saline springs, as some of the Warm and Hot Springs of Virginia, are excellent in the chronic rheumatism of children. La Bourboule, the famous French spring, is in high repute for these chronic cases, when no cardiac or pericardiac lesion exists. These waters are given in baths and douches, whose exciting qualities are very grateful to the atonic patient. Rheumatismal torticollis and hydarthroses are benefited also by saline baths. There are some more debilitated rheumatic cases where more stimulating treatment is called for. Send these to sulphur springs and combine massage with the baths (Simon).

Chorea.—In this rebellious and baffling disease the foreign pediatrists have found that a mineral water, such as St. Catherine's Wells, Ontario, which contain chloride of sodium in marked proportion, together with the bromo-iodides, often produces marked results.[2] The Ballston Spring (Franklin) is of this type, containing ninety-three grains of salt to the pint, as well as small percentages of iodide and bromide of sodium.

Intestinal worms.—Keating[3] recommends in these cases the Capon water. In eruptive diseases, where there is excessive thirst and scanty, high-colored urine, the same author recommends the lithia waters *ad libitum* (Farmville Lithia and Buffalo Lithia, No. 2). When constipation exists he recommends the alkaline-saline waters, as Saratoga seltzer.

As can be seen, saline waters occupy an extensive therapeutic field. They are more applicable to infantile diseases than the other waters, and in them alone we possess a valuable medicinal agent and adjuvant.

II. SULPHUROUS SPRINGS.—Their impregnation with sulphuretted hydrogen, to which their fetid odor is due, is the leading characteristic of these mineral waters. In addition, there is generally found some saline which modifies their effects. To the sulphuretted hydrogen they owe their efficacy in cutaneous diseases, and to the sulphuretted and saline ingredients together, their applicability to digestive disorders. The purely sulphurous are also tonic and stimulant. Luchon, Bonne, the famous Aix-la-Chapelle, and Baréges, in France, and Harrowgate, Bath, and Dax, in England, are of this type. America is rich in sulphur waters. We find them at the Red, White, and Sulphur Springs, W. Va.; Harbin Springs and Santa Barbara Springs, Cal.; Sulphur Springs, at Sharon, N. Y., and at Saratoga Lake, the Richfield, Blue Licks, Indian Springs, Ga., besides many others. The Bladon Springs, near Mobile, resemble Aix and Spa, but not so closely as the Rockbridge Alum Spring, Va., which may be prescribed wherever Aix water is indicated. This water is astringent and tonic, and is beneficial in chronic diarrhœa, bronchitis, dyspepsia, nasal catarrh, and scrofula. Another remarkable sulphur spring is the Oak Orchard Acid Spring, the water of which contains considerable quantities of free sulphuric acid, a rare composition. This water is particularly successful in chronic digestive affections, chronic pharyngitis, and ophthalmias.

It is in cutaneous diseases that sulphur springs are deservedly recommended. To be sure, as Dr. Coan remarks, we are here upon debatable ground. Those giants in dermatology, Hebra and Braun, as well as other respectable authorities, deny their efficacy, contending that skin diseases do not yield to mineral waters, but practical experience gives the "lie circumstantial" to this assertion. Especially is this curative power shown in old dartrous affections and in chronic skin-diseases of all types. An American spring highly praised in scrofulous dermatoses is that of Ocean Spring, Mo., and the Richfield Sulphur Spring ought to meet the same requirements, being one of the most powerful American sulphur springs.

Rheumatism, which is frequently overlooked in children, succumbs most often to a thermal sulphurous water (as Virginia Springs, Bath, Dax), the effect being due in large part to the perfectly equable warmth during the whole time of immersion—a thing impossible in an artificially thermal bath. Their additional tonic and stimulant properties give them value in anæmias, chloroses, and scrofulas which present chronic articular inflammations.

Scrofula.—Those springs at once sulphurous and saline are most applicable in scrofula. Where great debility coexists (accompanied by adenitis, cutaneous affections, or inflammation of the nasal or pulmonary mucous membrane) a feebly saline and strongly sulphurous water is called for, as that of Challes, France. The Red Sulphur Spring, Va., is greatly analogous to Challes, containing chiefly sulphur and an organic matter, with small quantities of salt. It is slightly cathartic and diuretic, and allays pulmonary irritation, as well as being sedative to the pulse, diminishing the beats. If, in addition, the spring contains iodine and bromine (as the Salt Sulphur Spring, Va.), so much the better. Cooper's Well is also of this nature, but the additional peroxide of iron renders it particularly efficacious in gastro-intestinal affections. Old and inveterate scrofulous lesions (fistulas, necroses, tumeur blanche, fungous arthritis) do well at Baréges, and some of the West Virginia springs correspond pretty closely to the analysis of Baréges.

Affections of the respiratory mucous membrane.—Sulphurous water is valuable in chronic bronchitis, and a sulphur water rich in sodium (as Eaux Bonnes, Ems, Sharon) succeeds "excellently well" in laryngitis (Coan). For nasal and pharyngeal catarrhs the Rockbridge Alum Spring can be given as a spray. Fine results are often obtained in children suffering from chronic suppurative otitis, blepharitis, ozæna, coryza, and amygdalitis from the use of Sharon water locally, In the commencing phthisis of children of the nervous and sanguine temperament, the Red Sulphur Springs of Virginia, which have already been discussed, are to be recommended.

Anæmia, convalescence, etc.—When the little patient is of herpetic constitution, he demands a sulphuro arsenical spring, as those of Aix. As yet I know of no such combination in American waters, though undoubtedly some exist. If vague, osseous pains are present, a thermal water is necessary; if atony and apathy, order sea-bathing or cold douches.

[3] Keating: Philadelphia Medical Times, July, 1886.

III. Gaseous or Carbonated Waters have a sharp, acidulous taste, lost on exposure to the air. They contain, with the carbonic acid, saline, earthy, or metallic matters (lime, magnesia, iron carbonates, etc.). Our leading springs of this class are the Saratoga, Ballston, Sweet, and Alleghany Springs, Va.; Rockbridge, Alum, Capon, Buffalo Lithia, and Highland Springs, Lake County, Cal.; Seltzer, Bar, Mont Dore, Néris, and Vichy are gaseous springs.

These waters increase appetite and are diuretic, hence they are successful in gastric disorders, dyspepsia, gout, hypochondriasis. The Rockbridge Alum Springs are particularly efficacious, benefiting also chronic diarrhœa, scrofula, and skin diseases. According to Coan the Ballston Spring is to be chosen for atonic dyspepsias, while for acid dyspepsias he prefers the Saratoga, Capon, and Buffalo Lithia water. Gastric catarrhs call for a Glauber's salt, as found at Carlsbad, Marienbad, and Tarasp. Highland Springs, Cal., contain soda, lime, and magnesia carbonates as well as large quantities of free carbonic acid and traces of silica, aluminum and sodium chloride, resembling Vals, an admirable water for infantile dyspepsias, flatulence, and gastralgia.

Simon, however, whose judgment in matters of infantile therapeutics is rarely at fault, confesses to a repugnance for strongly gaseous mineral waters. Nevertheless he orders them in obstinate nausea, disgust for food, and repeated vomiting, but with the proviso that their administration be continued not longer than one or two days.

Nervous diseases.—It is here that carbonated waters are eminently successful. Néris, in France, is famous for its cures of budding hysterias and chorea. Considerable caution should be displayed in the treatment of these infantile diseases, and it must be kept in mind that the careless use of mineral waters, douches, and sea-bathing, do nothing more than aggravate all the nervous symptoms. Nervous, irritable children, those with cerebral troubles, persistent headaches, or neuroses, cannot endure the seaside or the exciting mineral waters, *i.e.*, saline and sulphurous. The gaseous waters, on the contrary, are sedative. One of the best methods in such cases is to begin with simple thermal hydrotherapy, modifying temperature and mode of administration according to susceptibility. Some children endure cold douches well, but in no case should these be prolonged longer than from three to ten seconds. Bromide, the valerianates, and arsenic may be combined with this treatment. Infantile and diphtheritic paralysis require the stimulating waters, with massage and the constant current.

Scrofula is benefited at the Rockbridge Alum Spring, and incipient phthisis and the anæmia of the scrofulous are said to disappear under this water's influence.

IV. Ferruginous Waters are among the more frequent springs, and hold their iron (carbonates, sulphates, or chlorides) in solution by excess of acids. The carbonated iron waters are generally weak, while the sulphurous are powerful. The most famous are Tunbridge Spa, Schwalbach, Mont Dore (ferruginous and arsenical), Provins, Forges; Oak Orchard, N. Y.; Rawley, Va.; Ocean Spring, Miss.; Seigler and Harbin Springs, Cal.; Stafford and Columbian. In fact, nearly all waters contain some iron, and at every spring there is at least one ferruginous source.

As can be readily understood, these springs are of greatest utility in anæmia and chlorosis. One of the most famous in America is at Stafford, Conn., and is also, like the Oak Orchard Spring, N. Y., of peculiar efficacy in chronic diarrhœa, purpura, and passive hemorrhages. These waters ought to succeed admirably in summer complaint, and in that annoying and obstinate disease of childhood, rectal prolapse. In the hemorrhagic diathesis the alum and iron waters are most effective (Bartholow). Oak Orchard Spring has a peculiarly good effect upon relaxed and ulcerated conditions of the intestinal mucous membrane. It has a composition rarely found either in America or abroad, containing considerable quantities of free sulphuric acid as well as lime salts. Keating recommends it in intestinal atony, relaxation of mucous membranes (as in whooping-cough), and as a gastric stimulant after summer complaint. Saline chalybeates (as Warm Spring, N. C.; Lenk, Switzerland) are successful in scrofula, ozæna, psoriasis, and hepatic enlargement.

In prescribing ferruginous waters the intestinal functions must be under continual surveillance, and this more especially if alumina be present. Cerebral congestion must be kept in mind as a possible contingency, and where any such tendency is known to exist, extreme reserve in their administration must be observed.

V. Arsenical Springs are rare, but the presence of this element imparts to a mineral water wonderful curative properties. No springs in Europe are more extensively patronized than the three leading arsenical ones, La Bourboule (also saline), Royat, and Mont Dore. At Roncegno, Southern Tyrol, is a ferruginous-arsenical spring, and Vichy has traces of this element. These springs are rare in America. They are indicated in scrofula, rheumatism, and humid dermatoses. Intermittent fever, and that extreme chloro-anæmia which often accompanies chronic impaludism in the child, resisting all the effects of quinine or cinchona, frequently meet in arsenic and hydrotherapy curative agents of the first order.

Phthisis of scrofulous children, nasal catarrh, chronic bronchitis, and enlargement of the bronchial glands are improved by arsenical waters, as are also articular and rheumatic troubles, and some forms of nervous diseases.

In termination, we find that in mineral waters we possess a valuable therapeutic agent in many of the diseases of childhood. We make no pretension of having treated the subject, which covers so extensive a field, exhaustively. It is one which requires long and careful investigation, as well as many clinical observations in an interesting branch of materia medica. Physicians of this country have not given it the attention it merits, and until they do so the owners of springs will not awaken to the necessity of the improvements which are so often absent at such resorts in America.

Résumé.

	Principal Springs.		
Saline..	Hathorn. Vichy. Saratoga. Deep Rock. St. Catherine's. Warm, N. Cal.	General application.	Aperient. Tonic. Excitant. Feebly laxative. Alterative.
		Special application to children's diseases.	Scrofula. Rachitis. Articular inflammations. Chorea. Rheumatism. Anæmia.
Gaseous...	Saratoga. Ballston. Virginia Sweet. Rockbridge. Alleghany. Capon. Highland, Cal. Buffalo Lithia.	General application.	Digestive. Stimulant. Laxative. Diuretic.
		Special application.	Nervous diseases. Dyspepsia. Scrofula. Diarrhœa. Chorea. Hysteria. Gastralgia.
Sulphur. ...	Red Sulphur. Sharon. Richfield. Harbin, Cal. Blue Licks. Greenbrier.	General application.	Laxative. Sedative. Tonic. Digestive.
		Special application.	Cutaneous diseases. Digestive diseases. Anæmia. Scrofula. Rheumatism. Bronchitis. Laryngitis. Hepatic engorgements.
Ferruginous.	Oak Orchard. Stafford. Columbian. Sans Souci. Bedford. Rawley.	General application.	Reconstituent. Digestive.
		Special application.	Anæmia Chlorosis. Chronic diarrhœa. Purpura. Prolapsus ani. Dyspepsia. Hemorrhages.

FOUR CASES OF ACUTE INFLAMMATION OF THE MIDDLE EAR FROM THE USE OF ROOSA'S BULB NASAL INHALER.[1]

By FRANK W. RING, M.D.,

NEW YORK.

CASE I.—J. D. G—— came to me December 13, 1885. He had been to several physicians, and the last he accused of making him deaf. I found the following conditions: Hearing somewhat impaired, a deviated septum, hypertrophied turbinated bones, chronic pharyngeal catarrh, with excessive secretion, and an habitual mouth-breather. I removed several polypi, dilated the nasal passages, and put him on what I considered proper and judicious treatment.

Saturday, January 2, 1886, I made an application of iron and glycerine to the posterior wall of the pharynx, sprayed the throat and nose with Dobell's solution, and finally inflated the ears with the Politzer bag, using Roosa's pear-shaped cylinder bulb. The patient departed in good spirits, breathing freely. The next morning he came to my office early, with a pale and anxious countenance, after a most wretched night. An intense and excruciating pain had seized him during the evening, and had continued up to the moment of my seeing him. I immediately applied hot water, with no particular relief; then leeches were resorted to, which, placed upon the tragus, soon relieved him of his suffering. He was confined to his room for two days; upon the fifth he called, and I found the outer canal filled with blood and exudation. The canal was thoroughly cleansed, and the patient made a good recovery.

CASE II.—Miss M. S——, aged six years, first consulted me December 16, 1885, with a history of chronic suppuration of the left middle ear. Since two years of age the left ear had discharged pus at intervals of a few months. The hearing distance for the watch was $\frac{3}{40}$ in the left, and $\frac{30}{40}$ in the right. The child was timid, pale, and ill-nourished. I gave her proper tonics, advised plenty of milk, exercise, and fresh air. She continued treatment until January 2, 1886. Upon that day I sprayed her nose with Dobell's solution, cleansed the ear with peroxide of hydrogen, and inflated her ears with the Politzer and Roosa's pyriform bulb. During the night she suffered intense pain in the left ear. Her agony was so severe that a physician was called. He warmed some sweet-oil and laudanum, poured it into the offending ear and awaited results, which were not satisfactory, as the patient got little relief until four o'clock in the morning. Two days later I saw her at my office, when all symptoms of the acute inflammation had subsided. One month later the child was taken from my observation.

CASE III.—Master E. W——, aged five years. The patient came to me for treatment, December 29, 1885, with a history of chronic suppuration of the right ear of three years' duration. Hearing distance in right was $\frac{6}{40}$, left $\frac{30}{40}$; right ear was filled with pus and granulations. The ear was cleansed thoroughly with warm water and peroxide of hydrogen. After inflation the child heard the watch at eight inches, a gain of two. I saw the patient again the next day, and then on the 3d of January, an interval of four days. At eleven A.M., on Sunday the 3d, I used the Dobell spray, curetted some granulations from the right auditory canal, and inflated with the Politzer bag, using Roosa's bulb.

The child awoke in the night crying with pain in the right ear. Nothing the parents could do would relieve the agony, so they sent for the family physician, who applied heat and other remedies, quieting the pain and relieving the patient, so that in twenty-four hours all symptoms of the aural catarrh had subsided. Under the use of peroxide of hydrogen the suppuration ceased in a few weeks, and has not recurred up to the present time. It will be noted that the acute symptoms occurred in the sound ear, not in the suppurating one.

CASE IV.—Miss B. M——, aged six years, consulted me October 14, 1885. Since three years of age the child had had a suppuration of the right middle ear. The mother had been to several physicians, with no relief, and wanted me to state definitely the time it would take to cure her. The right external auditory canal was filled with pus, granulations, and cheesy matter. After cleansing and inflation the hearing distance was the same as before treatment, *i.e.*, $\frac{2}{40}$. In the left it was normal. The patient was immediately put on the peroxide-of-hydrogen treatment. The mother was taught how to use it, and did so faithfully until January 5th, when all discharge had ceased. The membrane was closed, hearing distance $\frac{4}{40}$ with the watch.

Upon this day, the last but one of her visits to my office, my only treatment was an inflation with the Politzer bag and pear-shaped nozzle. In a few days the mother called and informed me that "Bessie" had been very sick since her last visit, with terrible pains in her right ear, which came on the same night of the day she last saw me. The mother, fortunately, remembered my injunctions in regard to the treatment of such an accident, and relieved the intense pain with the hot-water douche. The child entirely recovered in a few days.

I have given a brief history of the four preceding cases, in order that the condition of each might be satisfactorily known. In two there were perforated membranes, in the others they were intact. No. I. came to me Saturday, January 2d, at twelve o'clock. The throat and nose were sprayed with Dobell from my air cylinder, iron and glycerine was applied to the posterior wall of the pharynx, and the ears were inflated with the Politzer bag and Roosa's pyriform bulb.

No. II. I saw the same day at 4.30 P.M. I used the Dobell spray, cleansed the ear with peroxide of hydrogen, and inflated with Roosa's inhaler as in No. I.

No. III. visited me Sunday, the 3d, at eleven A.M. I sprayed the nose, pharynx, and throat with Dobell, used the curette on some granulations in the external auditory canal, and inflated with the Politzer and bulb.

No. IV. I saw two days following. I did nothing but inflate the ears as in the previous cases.

On the 2d I had two cases of violent acute inflammation of the middle ear. On the 3d, another, and on the 5th a fourth, until the sight of an aural patient became obnoxious to me. It was intimated that I must have caused this suffering, as they had never experienced any such symptoms before.

In three cases I had used Dobell's spray, therefore it was not the Dobell which caused the trouble in the fourth, curetted in one case, which eliminated the curette from the others, the peroxide was acquitted under the same rule. The Politzer and bulb alone remained; they were used in every instance, and to them I attributed my unfortunate experience. The water which I use in my inner office is supplied from a galvanized iron tank, holding about six gallons. In inflating patient No. I., on Saturday, January 2d, I drew into the nozzle of the inhaler some mucus. Wishing to cleanse the instrument, I supplied the bowl with some water from the tank, not getting a sufficient quantity the vessel was inclined, so that I got considerable sediment from the bottom. I unscrewed the cap of the inhaler, expelled all the liquid, squeezed the sponge, replaced it, and screwed on the cap again, then the inflation was thoroughly made.

Four days later, the tank in the meantime having been filled, I drew off all the water, and found a thick sediment adhering to the bottom and lower sides of the vessel, the accumulated deposit of several months' use.

To me the cause of the four cases of acute aural catarrh was then quite apparent. The element of carelessness which entered into the proceedings was equally obvious, although I am sure there was no water injected into the pharynx in any case, as I had forcibly exhausted it from the tube.

---

[1] Read before the New York Academy of Medicine, Ophthalmological Section.

Had there been any doubt in my mind in regard to this, the account of these cases would not have been written, and, even allowing that the water had been injected on the first day, the tube was dry when the inflation was practised on the third and fourth patients, as I removed a portion of the sponge and placed it under the microscope on the 5th of January.

The question now naturally arises, What is there in the sediment of Croton water, which, after evaporation, should set up an acute aural catarrh if injected into the pharynx? There are algæ, *i.e.*, water-plants, infusoria or microscopic animals, bacteria, the lowest grade of animal organism, in multiform varieties. Were any of these germs pathogenic? Did they induce the catarrh of the mucous membrane in question? Last summer I had a number of cases of acute aural catarrh from salt- and fresh-water bathing, and only one was due to surf-bathing, in which instance the side of the head was struck forcibly by a wave, injuring the drum membrane. All the others were from still-water bathing, and where the purity of the water was questionable. It is not necessary to dive or force such water into the pharynx to bring on an acute catarrh, the same water is liable to produce the symptoms when used as a spray or douche. Therefore, it is not only the force with which it is injected, but also the character of the fluid.

We have in New York a system of free swimming baths, where the city's great unwashed go to transmit one to another any contagious malady with which they may be afflicted. These floating arsenals of contagion furnish a good proportion of the eye and ear diseases at our summer clinics. We also have various health resorts in the vicinity, where one may indulge in sea-bathing. Last summer I stood on the pier at Coney Island, in a stiff southerly breeze, watching the bathers disport in water freshly strewn with the contents of several scows from the city. Unloaded in this southerly wind, not two miles distant, decayed vegetable and animal matter could be easily seen floating about.

The north shore of Long Island Sound in Westchester County, and the inland bays of Monmouth County, N. J., are questionable bathing places. I had several cases of acute suppuration of the middle ear caused by bathing in these waters, so that now I always advise my patients to close the nose when they dive or go under the water.

Roosa says in his treatise on the ear: "Prolonged bathing and diving in still water are much more apt to cause congestion of the middle ear than surf bathing." Is it not because in surf bathing one gets less impurities in the water?

In closing, I would beg leave to call your attention to the following letter, sent to me by Dr. John E. Weeks, in reply to a communication in regard to the sediment of Croton water:

"In the continued deposit of a vessel used to hold Croton water we usually find a development of algæ, some infusoria, and a multitude of bacteria, including a greater or less number of varieties. Fortunately the forms that are detrimental when introduced in living tissues are seldom met with. However, it is impossible to say that any specimen of water is free from them, unless it has been previously boiled or analyzed. Croton water contains many germs. In an analysis extending over four months, I found that the number per cubic ctm. ranged from seventy-four to nine hundred and forty-five, the average was probably between two and three hundred. But few, if any, of the forms found, which numbered something over thirty, were in any sense pathogenic; in fact, I do not think that any that I have seen were capable of producing an inflammatory action. However, pathogenic germs may and do appear in water still preserving their vitality. I am inclined to think that purulent otitis from injections through the anterior nares is at times brought about by the presence of pathogenic or pyogenic germs which have been carried along with the fluid from the mucous membrane of the nasal cavities or pharynx into the Eustachian tube or middle ear. Pathogenic germs are very common on free mucous and cutaneous surfaces, remaining innocuous when the epithelium is intact. Your question is one that requires extensive investigation to enable one to answer it positively."

CONCERNING CHOLERA INFANTUM AND THE WEATHER.

By A. SEIBERT, M.D.,

PHYSICIAN TO THE CHILDREN'S DEPARTMENT OF THE GERMAN DISPENSARY AND INSTRUCTOR IN DISEASES OF CHILDREN AT THE POST-GRADUATE MEDICAL SCHOOL, NEW YORK.

In The Medical Record of July 21, 1888, Dr. T. Clark Miller, of Massillon, O., has published an article entitled "Cholera Infantum and the Weather," consisting chiefly of a number of criticisms of my report on an investigation concerning this question to the New York Academy of Medicine, and published in The Medical Record of March 24, 1888. My reply will at first treat of the method of Dr. Miller's criticism, and then of its results.

1. My critic says, in the beginning of his article: "The painstaking and elaborate study of this disease by Dr. Seibert is a very valuable addition to the literature of the subject;" and toward the end of his essay he remarks: 'But I believe his [Seibert's] reasoning from these facts to be utterly fallacious and misleading, and it seems to me many of his conclusions are squarely in the teeth of his data;" and further: "The learned discussion on the paper referred to in the Academy of Medicine is ample evidence that the subject is not exhausted, and it certainly cannot be said to be threadbare so long as it is possible for a great authority to question the superior mortality from this disease in July as compared with August."

The extreme inconsistency between this praise and fault-finding is so evident that no further reference need be made to it.

2. In looking for reasons and scientific arguments based upon acknowledged facts to sustain the above statements, we entirely fail to find them, and not even an attempt is made at drawing different deductions from the figures presented.

But my critic presents some statements of his own which are of interest: "What constitutes *hot* weather, there would be all shades of opinion, no doubt. If 75° to 80° F. be too high in the winter, in a hygienic sense, we may assume that it is a high temperature in the summer. The air we breathe ought not to be above 72° Fahrenheit." In reply: If 75° to 80° F. is *hot* weather, then it is strange that so few cases of cholera infantum occur in midwinter, in this city at least, for it is well known that our tenement house population, as a rule, keep the temperature of their rooms constantly nearer to 80° than to 70° during winter, and that the babies breathe this atmosphere for successive months, day and night. The air in these rooms is otherwise certainly in a much poorer hygienic condition in winter than in summer, with the windows open night and day, even at the same temperature, and yet cholera infantum and kindred diseases are extremely rare in winter in comparison with summer, which ought not to be the case if my critic's intimation that heat of 75° to 80° F. may produce this trouble in children by direct action on their systems be true. I will explain this conundrum. The milk used by these people and their children is, during winter, carefully kept outside of the window, and is constantly exposed to a temperature low enough to prevent, or at least retard, decomposition. If they kept their babies outside and the milk in the heated rooms, these children would get cholera infantum and like troubles as readily as in summer.

No doubt Dr. Miller has thought of the possibility of this argument, for, to counteract it, he makes this statement: "Infants may be affected at all seasons of the year by diseases having choleraic features; but it is clear that these troubles, occurring in the cool and cold months, are not at all related, pathologically, to the summer disease under consideration."

I must here admit my complete ignorance. I never heard of, read about, or saw, any pathological characteristic differentiating between summer and winter diarrhœa of children, and no doubt all pathologists will hail with pleasure this new addition to the pathology of the intestines, which is so clear to our friend.

In quoting from his interesting and valuable paper, published nine years ago (*Amer. Journ. of Obstetrics*, 1879), Dr. Miller points out the necessity of having tables showing three daily quotations of temperature in investigations of this kind, and speaks of monthly and weekly averages and reports as not satisfactory. Now I heartily agree with our colleague on this point, and my tables published show the three daily quotations of temperature for ten years, in comparison with my morbidity figures, and Dr. Miller's tables show but monthly and weekly averages and reports, and yet my results seem to him as "squarely in the teeth of *my* data."

Let us take one statement and see if the above is correct. It is true that Dr. J. Lewis Smith was surprised at the superior mortality from this disease in July as compared with August! But so was Dr. Cyrus Edson and Dr. Nagle himself, the latter the Registrar of the New York Board of Health, for these gentlemen had never added up their own figures, an omission others have since made, as I will presently show. But my figures regarding the mortality in this city were never *questioned* by anyone, as they can be verified at the Health Department at any time.

A greater surprise than the one spoken of, though, we now have ready for my critic. He has kindly published the weekly mortality statistics from cholera infantum of the city of Baltimore for the years 1879-1888. Desirous of gaining some "facts based upon figures," as in my former investigations, I simply compared the mortality of the July months with that of the August months. The figures are from Dr. Miller's article, but the adding has been done by me.

Mortality from Cholera Infantum in Baltimore.

	July as compared with August.	
1879	197	112
1880	169	65
1881	279	119
1882	237	72
1883	264	107
1884	224	76
1885	235	134
1886	242	102
1887	334	125
Total	2,181	912

This gives, in all, 2,181 deaths in July as compared with 912 in August, from this disease, making, on an average, 53 cases in each week of the July months to 24 cases in each week of the August months, being a proportion less than 2 to 1. My figures for ten years of mortality in New York were 12,468 for the July and 6,205 for the August months, 2 to 1, exactly as in Baltimore. How could it be otherwise? If 334 children die in Baltimore in one month, then surely there are 334 *less to get sick* the next month! I can leave it to others to judge whether or not my conclusions were "in the teeth of *my* data."

In conclusion I would, with all due respect, remind Dr. Miller that adding up statistics is a better and stronger argument than such terms as "I believe," "it seems to me," or "it is very clear," especially if they are to be used in criticising others, and intended for throwing more light on the subject under discussion.

Clinical Department.

THE PRIMARY TREATMENT OF LACERATED PERINEUM.

By C. E. Munn, Captain and Assistant Surgeon U.S.A.,

Fort Klamath, Ore.

During the past few years I have had the misfortune to witness in primiparæ under my care four cases of tears of the perineal body. My conscience acquits me of bad management, for in all the cases I foresaw the need of extra care. The patients were all past girlhood—the youngest twenty-four, and the oldest thirty-one years of age. The presentations were natural, and the first and second stages of labor slow from rigidity of the soft parts. As relaxants I used small (nauseating) doses of tartarized antimony and hip-baths, and lubricated the vulva and perineum well with sweet, cool lard or vaseline jelly. In all the cases I resisted the last uterine efforts with the tips of the fingers on the vertex, to insure slow relaxation of the thinning perineal crescent. There was very little effort made formally for what is called "supporting the perineum," yet I gently supported the advancing head as it rose under the pubic arch. In my last case, recently, the patient had been in labor many hours when I was called. She was a small, robust woman, thirty-one years of age, first conception, at the end of the ninth month of gestation. The sac of the amnion was broken. The head, presenting by the vertex in the second position, seemed fixed in the pelvis by its disproportionate size to the canal, and the rigidity of the soft parts. The vagina was well moistened by its natural secretions, which I was careful not to disturb by too frequent touching. At the twenty-eighth hour of labor I applied the forceps, and after nearly an hour of strong vibratory traction during the pains, the head was engaged at the outlet. As the patient was very tired, and doubting still her power of expulsion, I did not remove the well-locked blades, but used the instrument as an upward guide, and even for gentle repression during the last minutes. As the head was born I noticed a red jet, which I hoped was from the fourchette. The child, a female, was alive and uninjured, and weighed nine and one-half pounds. The patient was rested, and then, after delivery of placenta, neatly washed, her toilet carefully made, and placed in a clean bed. This was at the thirtieth hour, and the uterus was well emptied and thoroughly contracted. As all my cases were treated substantially alike, an account of the dressing and result of this case will serve for all.

After refreshment by light food, the mother was informed of her serious mishap, and requested to submit to a trivial operation. She was laid upon her left side, the hips elevated at the edge of the mattress, and a loose plug of absorbent cotton introduced into the vagina. The nurse supported the right buttock. My hands had been repeatedly washed in a warm solution of the bichloride of mercury, 1-2,000, and with similar clean solution I now syringed and washed the parts exposed to view. I found a deep, irregular rent, extending to the muco-cutaneous border of the anus. From previous care in cleaning forceps, parts, and hands, I believed the fluids from the vagina and the wound were aseptic, and the rent only required closing. This I did with three silk sutures, first soaked in solution and then introduced very deeply through the tissues and tied loosely, just tight enough to hold the parts in position. Before they were tied all clots were gently washed out with sublimated water. Then, over the line of incision, I applied about a teaspoonful or more of dry iodoform, covered it with a good, soft napkin, previously washed and dried from sublimated solution, withdrew the vaginal plug, and covered the napkin, lower belly, and inside of thighs with about a pound of cotton batting. The knees and inner malleoli were then padded with cotton, and the limbs firmly bound together. The abdominal binder was made long and was pinned tightly below the trochanters. She was instructed to urinate, without reference to the dressing, by turning on her side. On the fifth day, just before my visit, she had a soft motion of the bowels, which was received on a folded sheet. Having plenty of sublimated water and prepared napkins in readiness, the dressings were removed and her body quickly washed and dried and the sutures withdrawn; but, as the parts were not swollen, the dressings were reapplied and the limbs bound up again, to be loosened after four days more. On the fourteenth day I examined the parts carefully; the vulvar orifice showed no marks of being torn, the union was complete and firm, and the line of cicatrix hardly visible. In a former case I was privileged to examine the parts three months after I had operated, and found them absolutely natural. It would seem as if the fourchette tear had united. I would respectfully remark that "Peace hath her victories," and it seems to me than these cases were illustrations. I believe these accidents are very frequent. The wearied physician, after laying the child by its mother, feels that his work is well done, and ignores or treats with indifference a laceration which may fairly be presumed a natural consequence of parturition. At any rate, if recognized, they are seldom reported to the family or medical confrères. But that wound may serve as the open gate of septic infection, or, if saved from this, the torn woman may go through life unconscious of the great cause of her many distressful feelings.

From my experiences, few indeed, but sufficient for me, and from my success with simple treatment, I think that no practitioner will have fulfilled his whole duty by his lying-in patient until he has patiently examined the parturient parts for tears, and, if found necessary, taken careful measures for their immediate repair.

UNSUCCESSFUL VACCINATION AND IMMUNITY AGAINST SMALL-POX.

Dr. Winslow Anderson, of San Francisco, writes: "In reply to the query of Dr. W. Thornton Parker relative to the immunity against small-pox when not successfully vaccinated, as published in The Medical Record of June 23, 1888, I would relate several instances which came under my observation during the recent small pox epidemic in San Francisco.

"Case I.—The mother of a nursing infant was taken down with variola discreta. The child had nursed for three days after the eruption had appeared. When I was called in I immediately sent the patient to the Small-pox Hospital and vaccinated the infant. At the end of a week the vaccine virus produced typical umbilicated vesicles. The child did not contract variola.

"Case II.—An old gentleman had been exposed to the disease, having an inmate of his house sent to the hospital with whom he had been in daily contact. He was ninety-five years of age, and had not been vaccinated for forty years. I vaccinated him and it took successfully. He also escaped small-pox. I do not suppose that the vaccination had anything to do with the immunity in these cases, but it shows the resistance in different individuals.

"Case III.—A young woman had been vaccinated twenty-five times since her birth. At every small-pox scare she would try it again. At no time had the vaccination been successful. I vaccinated her myself three times during January, 1888, without any success. In the early part of February symptoms of small-pox appeared, and in three days she was sent to the hospital with quite a severe case of discrete variola.

"Case IV.—A man refused further vaccination, as he had been vaccinated eighteen times without any success whatever. Six of these unsuccessful operations had been performed during 1887–88. It was supposed that here was a case of "immunity," but not so. The disease was contracted, and the patient died within a month from the time he refused vaccination.

"Case V.—A patient who had been vaccinated unsuccessfully six times applied for a certificate of 'successful' vaccination. Upon refusing to issue it I made the seventh attempt. On the ninth day vesicles with typical areolæ appeared. On the eleventh day after the vaccination true variola appeared; the patient was sent to the hospital, and barely escaped death. Had the bovine virus not taken I believe she would have died.

"It seems wellnigh impossible to lay down any fixed rule. It is largely an *individual* matter whether a given person contracts the disease or not. One system may be more susceptible than another, and the same person may be more liable to contract the disease at one time than at another.

"I believe small-pox may be contracted, no matter how many times a person has been *unsuccessfully* vaccinated, and the only 'immunity' or prophylaxis known is *thorough* and *repeated* vaccination."

CONSTRICTION OF THE PENIS BY AN IRON RING.

Dr. D. W. Lynch, of West Bend. Wis., reports the following case: "On July 12, 1888, a boy, twelve years of age, worked an iron nut 1 inch square, $\frac{1}{2}$ inch thick, with a calibre of $\frac{9}{16}$ inch, on his copulative organ to its root. To his great consternation he was unable to remove it from its position, and his father's and mother's efforts also failed to dislodge it. He applied at my office six hours afterward for relief. The distal end of the organ was swollen three times its natural size. I sent for a blacksmith immediately, who came armed with a powerful lever shears and some files. The boy was laid upon the floor, the blacksmith gripped the nut between the blades of the shears, and with repeated efforts in a few minutes succeeded in cutting the nut at one point, when it instantly broke at right angles and flew off. The œdema soon subsided and left no injury."

HÆMOGLOBINURIA IN RHEUMATISM.

Dr. Albert H. Ashmead, of New York City, referring to a note on this subject quoted from the *British Medical Journal*, writes: "Permit me to report the following cases. The first case was that of a cook in a Cuban hotel in this city. He was a high liver, and hæmoglobinuria appeared during the second week and continued until the rheumatic poison was antagonized. Professor Loomis saw the case with me in consultation. Two cases occurred in my hospital service in Japan. One was typical, the other subsequently developed rheumatic purpura hæmorrhagica. A fourth case was seen in the Missouri Valley, near St. Joseph, Mo., in the fall of 1878, the year of the yellow-fever epidemic. All during that fall the malarial fevers peculiar to the upper river valleys had been more severe than usual, and had shown a hemorrhagic tendency. This case was apparently typical, but may possibly have been complicated by the low malarial influence."

TRAUMATIC AMPUTATION OF LEG—STUMP UNDRESSED FOR EIGHT DAYS—RECOVERY.

Dr. T. J. Hutton, of Fergus Falls, Minn., writes: "Five years ago I treated this case, which is worthy of being placed on record. A family had recently arrived from the mountains of Norway, where life is chiefly pastoral, and both broad acres and farm machinery are unknown. The sickle of a mower at work seemed to fascinate a member of this family, a boy, aged nine. He followed it up and kept kicking at it with his feet—first one foot, then the other. Either failing to keep step, or because the unexpected must happen, the sickle amputated his left leg at about the union of the middle and lower third. It made a clean cut, leaving a long ovate stump. A bystander stated that upon receiving the injury the boy hopped rapidly in a bee-line, about four rods, upon the sound member, then suddenly assumed the dorsal decubitus, raising his stump straight up in the air. The family was both ignorant and poor—did not even know that surgical aid could be obtained at the public expense, and so it happened I was not called until eight days had elapsed, and nothing had been done for the boy save that an old woman had tied a rag around the stump. A grayish pellicle covered the stump. There was no swelling, gangrene, fetor, or sepsis. There was great weakness—that was all. I remained with him twenty-four hours, administering wine, quinine, and concentrated food at short intervals. I then reamputated. He made a speedy recovery, being out-doors within a week."

Progress of Medical Science.

Ectocardia.—According to the Paris correspondent of the *Medical Press*, M. Lannelongue made a communication before the Académie des Sciences on a case of ectocardia. A little girl, of six days, was brought to him in February last at the hospital for "something that the parents could not understand." The child, although weakly, seemed to be in fair health and took the breast well; but on the middle of the sternum there existed a circular ulcer a little larger than a shilling, at the bottom of which the ventricles were felt to beat, but a sort of membrane concealed the heart from view. A week subsequently this membrane was destroyed by ulceration and then the apex of the heart could be plainly observed, the surface of the ventricles being entirely exposed. M. Lannelongue by an auto-plastic operation was able to effectually close the aperture, and at present the child seems to be in excellent health.

Electrical Sunstroke.—A number of cases are now on record of effects produced by the electric light identical with those resulting from prolonged exposure to strong sunlight. At the Creusot Iron-Works the skin of the workmen becomes reddened and tender, and this is followed by desquamation. The eyes became painful and suffused, and the retina, notwithstanding the use of very dark glasses, lost its sensitiveness, and the visual images appeared for some time after to be tinged saffron yellow. As a result of some inquiries it appeared that a current intensity exceeding two hundred ampères is liable to give rise to the preceding symptoms. The ocular symptoms are occasionally somewhat alarming, but they are fortunately characterized by a tendency to prompt amelioration.—*Medical Press.*

Duodenostomy and Gastro-Enterostomy. — Dr. Jesset has recorded two cases of this kind in *The Lancet.* In his opinion one of these cases showed that such an operation in cases of extreme urgency is not only practicable, but without doubt a great source of comfort to the patient; the other case of gastro-enterostomy demonstrated how perfectly a fresh channel between the stomach and intestine may be established, and, notwithstanding the most adverse circumstances, how firmly the serious membrane of the stomach and jejunum unites in an extremely short time. The questions naturally arise: Are these operations justifiable? Is it worth the trouble, anxiety, and risk to subject a patient suffering from cancer or extreme stenosis of the pylorus to such a formidable operation? Both these questions he is inclined to answer in the affirmative, and for the following reasons: 1. We are dealing with a disease that of necessity will destroy life, not in the ordinary way, but by the most cruel and horrible process of starvation, accompanied by frightful agony. 2. The constant excruciating pain, coupled with the frequent and violent vomiting and total inability to take any food, renders the patient's life a perfect misery to himself and all around him. 3. By operation, if undertaken early enough, undoubtedly life may be prolonged if the operation is successful, and the last days of the victim will be considerably relieved of the pain. He would in no case recommend duodenostomy to be performed if the patient's strength was sufficient to allow of his undergoing an operation of such a prolonged character as gastro-enterostomy would entail, as undoubtedly by this operation the patient is placed in a far more satisfactory condition than by any operation that has for its object the opening of the small intestine for the means of feeding. This must be self-evident, as in gastro-enterostomy there is no interference with the process of digestion and the secretion of the liver and pancreas, as well as the admixture of the food with the saliva during mastication. These secretions thus mingling with the food in the natural manner, the process of slow starvation is prevented, to say nothing of the unpleasantness of the patient having to be fed by an artificial opening in his abdomen being avoided.

Phthisis a Disease of the Night.—Dr. Shepherd contends in *The Lancet* that phthisis is the result of constantly recurring irritation of the air-passages, and that the cold air breathed at night is at least one efficient cause of this irritation. He observes that it is well known that those who live most in the open air are the least likely to suffer from phthisis. Why? Simply because their lungs are so accustomed to cold air that they are not irritated by it at night. Phthisis is a disease of the night. It is so simply because we inhabit hot rooms by day and cold rooms by night, and many lungs find it more than they can do to accommodate themselves to the constantly recurring change in the temperature. The author concludes as follows: "It will be obvious that my theory has a very practical bearing. If it should lead the profession, and the public through them, to pay proper attention to the due warming of our bedrooms at night, and all night long, especially in all cases of diseases of the chest, I shall not have written in vain. If through this simple precaution it should be found that phthisis in this country may thereby be stamped out in the course of a few years, then my humble name would perhaps deserve to rank with even that of Jenner. I fully believe that if some means whereby a continuous supply of pure warm air could be given at night to those threatened—ay, and to those actually suffering—with phthisis, we should in the course of a very few years find that phthisis was as rare in England as in Egypt or Iceland."

Guaiacol in Phthisis.—In the treatment of phthisis Professor Fränkel recommends guaiacol as the effective constituent of creasote. The good effects of the latter are unmistakable in a strictly defined class of cases. If used promiscuously in this disease, its good effects are distinctly evident in sixteen or twenty out of four or five hundred cases, and are due not to destruction of the bacillus tuberculosis, but to a favorable influence on digestion. It has long been known that creasote is a mixture of different substances, and last summer Professor Penzoldt remarked that guaiacol appeared to be its chief therapeutical constituent. Since then Dr. Sahli, of Berne, has written on the clinical uses of guaiacol, and Professor Fränkel has been using it since the beginning of the year after the following formula: Guaiacol, 13.5; tinct. gent., 30; sp. vini rect., 250; vini xerici, q. s. ad colat. 1,000—a dessert-spoonful in a wine-glassful of water two or three times a day. This mixture is superior to gelatine capsules or tolu balsam. Fränkel remarks that his patients were nearly all hospital patients carefully watched, only nine being private patients.

A Deaf-mute Ball-player.—One of the noted ball players of a professional nine is a deaf-mute.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM WOOD & Co., Nos 56 and 58 Lafayette Place

New York, August 11, 1888.

THE PATHOGENIC CONDITIONS OF ALBUMINURIA.

THE study of the conditions which are capable of determining the passage of albumin from the blood into the urine is one which has always interested the medical mind, and the literature of the investigations, both clinical and experimental, made to solve the problem presented is voluminous. The results of these investigations, however, have not hitherto been wholly satisfactory, owing, possibly, as Professor Semmola suggests, to the fact that most of these investigators have started out with preconceived ideas to which they have unconsciously endeavored to mould the facts observed.

Professor Semmola, whose theories, if not invariably acceptable, are always deserving of respectful consideration, endeavors to throw some new light on this subject in an article embodying the results of additional researches, published in *La Riforma Medica*, Nos. 25 to 36, 1888. One thing, which he thinks has helped greatly to befog the question and to vitiate the conclusions of many of those who have studied the subject, is the notion of a normal or physiological albuminuria. This idea he combats at the outset, maintaining that the appearance of albumin in the urine, no matter in how small quantity or for however short a period of time, is always pathological. Albumin and sugar both circulate in the blood, and are both destined for the nourishment of the body and for the maintenance of its functions; but neither the one nor the other is, even in the most minute quantity, normally excreted by the kidneys, and when either is so excreted it is the expression of a pathological condition.

Three factors are to be considered in the study of albuminuria, viz., the mechanical conditions of the circulation, the physico-chemical constitution of the blood, and the histological condition of the kidneys. It is necessary to determine, first, to what degree these three factors are efficacious in causing the passage of albumin into the urine; and then to apply the knowledge thus obtained in each individual case, in order to determine which of these factors is here most active.

The author devotes little space to the consideration of the second of these factors, since his views in this respect are well known. He asserted many years ago that, when the normal serum-albumin circulating in the blood becomes changed from any cause, it becomes unfit for the nourishment of the tissues, and is thereupon excreted by the kidneys, just as is any other poison or waste-product either formed within the system or introduced from without. This was indeed, he believed, the primary cause of Bright's disease, the renal changes being secondary and produced by hyperæmia and subsequent inflammation resulting from the excessive labor thrown upon the kidneys in their endeavor to excrete the large amount of albuminoids circulating in the blood. We shall see to what extent he has modified this extreme view, and how far he now admits the other conditions as factors in the causation of albuminuria.

It has been generally held that an increase in the blood-pressure within the glomeruli of the kidney is capable of causing the escape of albumin into the urine. Nevertheless, the experiments on animals made to determine this point have not always been confirmatory of the theory, and the results of clinical study have seemingly contradicted it many times. Often, in cases of heart disease, in which all the conditions most favorable for a passive congestion of the kidneys are present, not the least trace of albumin is found in the urine. From this the author concluded that some other factor must intervene to determine the occurrence of albuminuria, since it was shown that increased blood-pressure alone was not always sufficient to cause it. In order to determine the effects of increased blood-pressure he made a number of experiments upon dogs. The blood-pressure was increased by means of direct transfusion from a large dog to a smaller one, the author believing that this method was less likely to induce general disturbances, thereby complicating the experiments, than was ligature of the aorta or other large arteries. Furthermore, a general increase of the blood-pressure, such as occurs in the human body in various diseased conditions, was obtained in this way. These experiments showed that an increased blood-pressure caused first polyuria and then hæmaturia, but albumin was present in the urine only in proportion to the amount of blood, and albuminuria without hæmaturia was not found. The author then made another experiment, injecting into the vein of one dog, by direct transfusion, a certain quantity of blood, and into another a nearly equal amount taken from the same animal, but previously defibrinated. Thus the conditions in the two cases were dissimilar. In one the blood injected was unaltered, in the other it was dead, and may well be assumed to have undergone essential changes in its constitution. In the first dog the results were the same as those obtained in the first series of experiments—that is, there was hæmaturia, but no albuminuria, properly speaking. In the second dog, into whose veins defibrinated blood had been injected, the urine was not reddened, and very few blood-corpuscles were found on microscopical examination, but there was a large amount of albumin. The kidneys in the first dog were found to be nearly normal, while those of the second were markedly altered, showing necrosis of the epithelium of the tubules and many casts. In all of these experiments the urine was examined before the transfusion was practised, and was found to be normal.

As a deduction from these experiments Professor Semmola concludes that patients with cardiac trouble, whose urine contains albumin, suffered from albuminuria prior to the advent of the circulatory disturbances consequent upon the heart disease. In proof of this proposition he took a healthy dog and injected daily into the circulation a certain amount of egg-albumen. The animal soon began to pass albumin in the urine. The author then practised direct transfusion from another dog, as in the previous experiments, with the result of increasing the amount of albumin excreted through the kidneys. He concludes, therefore, that the effect of heightened blood-pressure is to cause an increase in the degree of albuminuria already present, but not to excite it in those whose urine was previously normal. In this way, also, he explains the fact, often observed, that after the circulatory disturbances consequent upon heart disease have been relieved by appropriate treatment, the amount of albumin in the urine diminishes but does not wholly disappear. The influence of the increased blood-pressure is no longer active, but the pre-existing albuminuria remains as before.

The third factor is the pathological change in the kidneys. That the amount of albumin in the urine is not determined solely by the pathological conditions in the kidneys is shown, the author thinks, clearly enough by the fact that it varies greatly according to the quality of the food, a diet consisting largely of nitrogenous materials causing an increase, and a non-nitrogenous diet a decrease. It is also shown by the fact that extensive renal lesions are often found post mortem, although during life not even a trace of albumin was found in the urine. Dr. Semmola does not, however, deny absolutely the power of kidney lesions in producing albuminuria. He has no new experiments to relate, having simply repeated those of Cornil and others, but he interprets in a somewhat different manner the results obtained. To produce experimental nephritis he made use of cantharides. In chronic cases of poisoning by this substance, the lesions noted were most marked, but the albuminuria was very slight—out of all proportion, indeed, to the pathological changes. The quality, also, of the albumin, as well as its quantity, differed from that in the hematogenous, and, according to Semmola, the most common form, of albuminuria. In this form the substance excreted is the dializable albumin of the blood, and the process is one of filtration pure and simple. In the other form, the nephrogenous, on the contrary, it is the albumin of inflammatory exudations. It does not possess all the reactions of the serum-albumin, and especially it does not assume the reddish-violet color in the presence of oxide of copper dissolved in caustic potash.

The conclusions of the author are, therefore, briefly, as follows:

1. The excretion of albumin in the urine has as its fundamental condition certain alterations in the albuminoids of the blood, which render them unfit for assimilation; they must, therefore, be eliminated by the different emunctories, of which the kidneys are the chief. All the cases of so-called physiological albuminuria belong in this category.

2. Increase in the blood-pressure alone is incapable of causing the appearance of albumin in the urine, but it may increase the degree of a previously existing albuminuria.

3. Pathological changes in the kidney produce albuminuria only when they are the result of an acute or chronic inflammatory process. In cases of nutritive disorders of the kidney, such as amyloid disease, the albuminuria depends, not upon the renal lesion, but upon the general nutritive disturbance, of which the kidney disease is but one of the effects.

THE TONGUE AS A GUIDE TO THE DIAGNOSIS OF LESIONS OF THE INTRA-CRANIAL VESSELS.

THE inspection of the tongue is part of the routine of every clinical examination, but it is often little more than routine, and, beyond making a mental note of the amount and color of the fur, and of the degree of moisture of the surface, the physician ordinarily pays little heed to the condition of the organ. But even this cursory examination is usually confined to the upper surface of the tongue, and an inspection of the under surface is seldom made.

In a communication made at the recent meeting of the French Association for the Advancement of Science (*L'Union Médicale*, May 26, 1888), Dr. Gillot refers to the neglect of this portion of the tongue, which, he asserts, often presents certain points of diagnostic significance to reward the physician for his trouble in inspecting it. It is the condition of the superficial ranine vessels, especially, which is to be studied in this inspection. In a young and healthy person the veins alone are prominent beneath the mucous membrane, but with the advance of age, or as a result of disease, these veins become dilated, tortuous, or varicose, and the venules and capillaries become visible. In many cases little dilatations, like grains of sand, may be seen on the smaller vessels. These may be so minute as to be detected only with the aid of a lens, but are ordinarily readily visible to the naked eye as little projections the size of millet-seeds. They may be few and disseminated, or may be very numerous and grouped together like a bunch of grapes. They are ordinarily situated a short distance from the tip of the tongue, on either side of the median line, or near the root of the organ. Their color varies, according to their size and the condition of the general circulation, from a bright red to purple, or almost black.

These projections, Dr. Gillot states, are true miliary aneurisms caused by a thinning of the walls of the vessels, and are analogous to the miliary aneurisms occurring on the cerebral vessels. But more than this, they are diagnostic of this condition in the vessels of the brain, or at least should raise a grave suspicion of its existence. The circulation of the tongue has very close relations with that within the cranium, the same influences which act upon one acting also upon the other, and the inspection of the under surface of the tongue furnishes as valuable an indication of the state of the cerebral circulation as does an examination of the fundus of the eye, while it can be readily made without instruments and does not require of the physician any special training, as does the use of the ophthalmoscope.

The primary cause of these miliary aneurisms, of the tongue as well as of the brain, Dr. Gillot refers to the so-called arthritic diathesis, and he says that he has never seen these minute dilatations of the lingual vessels in any but those suffering from arthritism, a term used to denote the diathesis expressed by the manifestations of gout, rheumatism, gravel, cardiac affections, etc.

The author urges a careful inspection of the under surface of the tongue in the aged and in those presenting any lithæmic symptoms, and believes that the physician may, thereby, often derive much assistance in the diagnosis of disturbances of the cerebral circulation, and may also obtain very valuable indications for treatment, being often enabled to avert, or at least postpone, grave cerebral disorders by timely and judicious treatment.

THE DANGERS OF "PADDLING."

At almost any of the seaside resorts numbers of children, usually little girls, may be seen, with their clothes tucked up around their hips, wading out as far as the length of their little legs will permit. It is a pastime in which they take great delight, and it seems really cruel to attempt to deprive them of it. Dr. Raven, however, has no such compassion for them, and writes to *The Lancet*, pointing out the danger to health in this sport. The water around the legs is cold, and the sun beating upon the head and trunk is hot, and the common result, this writer states, is a condition resembling heatstroke. The victim is feverish and restless, complaining of headache and nausea. The head is hot while the extremities are cold. Jactitation of the limbs is commonly seen, and vomiting is a frequent symptom. The conjunctivæ are congested, and there is intolerance of light and sound. Twice he has seen peritonitis brought about by this practice, and in several cases the symptoms attributed to "paddling" have been sufficiently serious to cause anxiety. It is surprising that, among so many offenders, there should be so few sufferers; but the symptoms in many cases, he suggests, may not be sufficiently severe to render the attendance of a medical man necessary. If the children must wade, as probably they will, Dr. Raven says that a degree of safety is insured by making the child leave the water frequently, and run about on the shore. The limbs thus become warm again, and some danger is avoided at the expense of the skin, which is apt to become inflamed and blistered by the sun. This, however, is a minor evil.

The treatment which he employs in cases of heatstroke from "paddling" is to make the patient paddle, as it were, at the other end. That is, to immerse the extremities in hot mustard and water, while douches of iced water are applied to the head. To relieve congestion of the internal organs, a brisk purge is generally needed.

An Army Medical Board will be convened in New York City, October 1, 1888, for the examination of candidates for appointment in the Medical Corps of the Army. Application for an invitation should be addressed to the Secretary of War, stating date and place of birth, place and State of permanent residence, and accompanied by certificates, based on personal acquaintance, from at least two persons of repute, as to citizenship, character, and moral habits; testimonials as to professional standing, from the professors of the medical college from which the applicant graduated, are also desirable. The candidate must be between twenty-one and twenty-eight years of age, and a graduate from a regular medical college, evidence of which—his diploma—must be submitted to the Board. Further information regarding the examinations and their nature may be obtained by addressing the Surgeon-General U. S. A., Washington, D. C.

News of the Week.

A new position at the Boston City Hospital has been created, namely, that of ophthalmic and aural interne.

Dr. Raphael, of this city, died in Saratoga on August 4th, after a brief illness.

Dr. Kálmán Balogh, of Buda-Pesth, professor in the University and dean of the Medical Faculty, and a knight of the Order of the Iron Crown, died in that city on July 15th, aged fifty-three. According to *Orvosi Hetilap*, Professor Balogh was truly a self-made man, for his path to eminence was smoothed before him by neither relative nor noble patron, and all the honors that he acquired were earned by his own exertions.

The German Physicians of the Late Emperor.—The German Emperor has conferred on Professor von Bergmann the Star and Cross of the Royal Order of Hohenzollern, and on Professors Gerhardt and Schrötter the Order of the Red Eagle (of the second class).

Dr. F. Bramann, first assistant in the University Surgical Clinic, who performed tracheotomy on the late Emperor Frederick, has qualified for the position of *Privatdocent* in the University of Berlin by an inaugural dissertation on "Myotomy and Tenotomy To-day and in the Pre-antiseptic Period."

The Medical Department of the Minnesota State University has absorbed three of the medical schools of St. Paul and Minneapolis, but the fourth, the College of Physicians and Surgeons in the latter city, has not joined the new arrangement, and evidently has no intention of doing so. The project has given rise to much discussion, which seems to betray a certain lack of harmony in the medical profession of the sister cities of the Northwest.

The position of the layman expert on patent medicines in the courts is a vague one. In civil cases his evidence is often admitted; in criminal cases it is as often excluded. The last occurred in a case tried some years ago in Chicago. A member of the Eclectic Society was expelled for violating its code of ethics by advertising a patent medicine. He brought a suit of criminal libel against the president of the society. During the proceedings several lay witnesses were called to testify to the virtues of the medicine. Their testimony was excluded on the ground that they were not experts, and consequently not capable, legally, of giving evidence on the subject. Lay evidence is admitted to the columns of the secular and religious newspapers, and that to the nostrum-venders is of most the importance.—*Medical Standard.*

The Massachusetts Health Board, during the past year, examined 4,870 samples of food, of which 35.05 per cent. was found to be adulterated or not conforming to the statutes, including 3,080 samples of milk, of which 38.33 per cent. was below the standard or adulterated. Of 550 samples of drugs, 400 were of good quality. In the five years—1883 to 1888—of the operation of the act, the percentage of adulteration found has been reduced very materially, and in milk from 83.9 to 38.33. An extended report on oleomargarine shows that it is probably not quite so digestible as butter, but is very nearly as nutritious, and does not so readily become rancid; that it is wholesome if properly made of good material.

Experiments with the Alternating Electric Currents.—Drs. Cyrus Edson and Charles F. Roberts, of the Board of Health, made some experiments at the School of Mines of Columbia College, August 3, at the request of Mr. Harold P. Brown, Electrical Engineer, to determine the danger of alternating currents. Two dogs were exposed to the action of alternating currents of 272.16 and 340.5 volts respectively, for five seconds, the number of alternations being 288 per second. Each dog was motionless during the continuance of the current, and died soon after. A third dog was submitted to a current of 220 volts for five seconds, but was not killed. He was then exposed to the same current for thirty seconds, and died at once without a sound or struggle. Those present were convinced that the deaths were painless.

Trichinosis in New York.—Two cases of trichinosis have recently been reported to the Board of Health by Dr. Seibert of this city. The persons affected are a man and his wife. The woman was taken sick about twenty-four hours after having eaten some raw beef which had been passed through a pork-chopping machine. The husband was attacked eight hours after his wife. Dr. Edson of the Health Department agreed with the reporter in the diagnosis. The unusual feature of the cases was the short prodromal stage in each instance.

Cerebral Surgery.—Mr. Damer Harrison states that so far there have been forty-one recorded operations for the removal of cerebral tumors, or opening of cerebral abscesses, with only seven deaths. Mr. Jacobson collects seventy cases of operations for cerebral hemorrhage, with fifty-seven deaths.

A Vigorous Centenarian.—On August 5th, Mr. George L. Perkins, of Norwich, Conn., celebrated the rounding out of one hundred years of his life. He is still in full possession of all his mental faculties, and walks to his business every day as regularly as he did half a century ago.

Looking for Practice.—The following advertisements from the *London Times* would seem to indicate that the rising young physicians in England are not devoid of ingenuity, even though their self-respect be not great: "A Young Medical Man, of great abilities and high testimonials, is, from want of means, prevented from obtaining a practice. Would any benevolent lady or gentleman of influence assist him by obtaining an appointment or otherwise? Address," etc. "To Philanthropists.—Young Doctor, highest credentials, living West End, will attend, gratis, limited number of patients annually recommended by any philanthropist paying sufficient for rent and taxes."

Deaths from Alcoholic Excess in London.—Dr. W. Wynn Westcott, a deputy coroner of London, publishes in *The Lancet* an analysis of 1,220 consecutive inquests held by him in that city. He is, he says, neither a total abstainer nor an advocate of that cause, and therefore thinks that he may be free from the charge of having exaggerated the figures. Of 1,220 cases of death, including deaths from violence, sudden deaths, persons found dead, and death with regard to which no medical certificate is forthcoming, 470 were infants, children, and persons below the age of sixteen years. These may be presumably removed from the list of deaths from alcoholic excess. Of the remaining 750 deaths, no less than 143 are recorded as being the result of chronic alcoholic disease, acute alcoholism, delirium tremens, suicide caused by drink, or of accidental death while drunk, or of accidents arising because of incapability when intoxicated; that is, one death in every 5.24. Of these 143 cases, 86 were men and 57 women. Of these 143 cases, 21 were suicidal, 23 accidental, and 99 the result, more or less sudden, of syncope, apoplexy, etc., due to disease of the heart, liver, and kidneys, stated in sworn evidence as due to alcoholic excess. Of the 143 cases, 9 were suffocated during the stupor of alcohol, 3 died in the act of sexual intercourse from syncope due to degenerative cardiac muscular tissue, and three were run over by vehicles in the streets. Only 9 of the cases were of persons under thirty years of age, but 21 cases were of persons over sixty years of age. The results of this investigation show that there is still a wide field for useful exertion in the cause of temperance.

The Antipyrine Craze in Paris.—Dr. Warren-Bey writes to the *Virginia Medical Monthly* that the extent to which antipyrine is employed in Paris is incredible. The average French doctor prescribes it for all the ills that flesh is heir to; it has become as necessary an article in every lady's boudoir as her perfume-bottle; scarcely a man can be found who has not some of it carefully stored away in his pocket-book; children are raised on it, and cry for it as for their *biberons;* and, in fact, they all take it, and for all things, but especially for *migraine*, which, as you know, is pre-eminently the malady of those who indulge in social dissipation. "That you may form an idea of the extent to which it is the rage, I will give you an incident as it was told me by the party immediately concerned: Mrs. P.—— was dining out recently in the Faubourg St. Germain, when she chanced to mention that she had suffered with headache during the day. Instantly, from the pockets of thirteen of the fifteen guests who were present, antipyrine was produced—in capsules, wafers, powders, and elixirs—and she was compelled to take a dose then and there, notwithstanding her earnest protest, and her assurance of entire relief before starting from home."

The habit of discussing fees is considerably ingrained upon some American physicians. According to Dr. Warren-Bey, the French set a good example in this matter. Nothing, he says, offends a French physician more than an inquiry in regard to his charges for professional services or for money to be directly paid to him. Although at heart extremely solicitous respecting his fees, he considers it *infra dig.* to discuss them, and he expects every client to take a hint from the louis conspicuously displayed upon the mantel-piece, and to add his quota to them before leaving the room. In consultations it is the duty of the regular physician to obtain the fee—one hundred francs in ordinary medical cases—and then to hand it to the consultant, sealed up in an envelope, in the most quiet manner possible, and never in the presence of the patient or his family. No conversation on the subject is admissible, and the matter is treated as if it were the least important thing in the world. One excellent custom in connection with consultations prevails here: the regular physician, as well as the consultant, receives an extra fee—usually a double one.

Society Reports.

SURGICAL SOCIETY OF PARIS.

Stated Meeting, July 11, 1888.

(Special Report for The Medical Record.)

M. Polaillon, President, in the Chair.

M. Quénu presented a communication on the

TREATMENT OF COLD ABSCESSES BY IODOFORM INJECTIONS.

In a recent discussion on the occasional untoward effects of the injection of an ethereal solution of iodoform for the cure of cold abscesses, it had been asserted that poisoning occurred only when some lesion of the kidneys or liver existed. This, the speaker said, was true in a great majority of cases, but that it was not so always was shown by a case which he had just seen. A young woman, aged eighteen, came to consult him on account of a cold abscess of moderate dimensions. He injected an ethereal solution of iodoform which gave rise to alarming symptoms of poisoning. The urine had been previously examined with the greatest care, and was found to contain not a trace of albumin or sugar. The other abdominal viscera were also normal, as far as could be determined by the most painstaking investigation.

M. Richelot reported a case of

CYST OF THE VAGINA,

which was interesting by reason of the uncertainty of diagnosis which existed for a time. The cyst had its origin in the lateral cul-de-sac on the left side, and was of enormous size, filling the entire vagina and even projecting from the vulva. The cervix was found high up on the right side of the tumor, and apparently had no connection with it. The cavity of the uterus measured nearly three inches in depth. When an attempt was made to delimit the tumor it was found to be sessile and covered with the mucous membrane. A puncture gave exit to a thick fluid, and thus established the diagnosis of a cyst, which had before not been certain. The tumor, which was found to be of embryonal origin, was enucleated. But, on account of the redundancy of tissue in the vaginal wall, a prolapse occurred, and it was found necessary later to resort to a colporrhaphy for its cure.

M. Schwartz read a communication on a case of

PRESSURE PARALYSIS FROM A CALLUS,

reported by M. Marchand. A man, aged twenty-nine, had been thrown from a horse, sustaining a fracture of the upper end of the fibula with posterior luxation of the tibia. A plaster-of-Paris splint was applied, but when it was removed, at the end of six weeks, the patient was found to be suffering from various disturbances of motion and sensibility. The foot was in an equinos position, and anæsthesia and paralysis existed in the parts supplied by the external popliteal nerve. The electrical contractility was abolished, and a marked degree of atrophy existed. There was considerable callus at the seat of the fracture of the fibula, and pressure here caused pain. Thinking that the nerve might be imprisoned in the callus, M. Marchand laid bare the tumor and discovered the external popliteal passing over it. On following up the trunk of the nerve it was found to be embedded in a mass of hard fibrous tissue. When freed from this adventitious sheath the nerve was seen to be enlarged at this part, and congested. The wound healed readily, but the function of the leg was not immediately restored. Gradually, however, motion and sensation began to return, and, rather curiously, the power of voluntary movement was gained before the restoration of electrical contractility. At the end of seven months the patient's condition was nearly normal.

The author referred to the rarity of this accident, but called attention especially to the exceptionally good results which followed the liberation of the nerve. In some of the cases previously reported, slight or no improvement was obtained by operation, and in others neuritis occurred, necessitating amputation.

M. Bouilly reported a case of

TUMOR IN THE RIGHT ILIAC FOSSA.

The patient was a woman, aged forty-four, who had been suffering during the past five years from attacks of abdominal pain and vomiting, which had gradually become more severe and frequent, being finally excited by the least exertion. The woman was unable to eat anything, had become greatly emaciated, and was in a truly pitiable condition. Eight months before coming under observation she had discovered a swelling in the right iliac fossa, which was slightly painful on pressure, but which had not increased perceptibly in size since it was first noticed. The tumor was of about the size of a man's fist, immovable, but not adherent to the superficial tissues. The patient was kept fasting for two days, after which laparotomy was performed. The tumor was found involving the ileo-cæcal portion of the intestine, and loosely adherent to the pelvis, from which it was, however, readily detached. The portion of intestine involved in the tumor was resected, and the growth was removed. The Czerny-Lembert suture was used to unite the divided ends of the intestine, and perfect occlusion was obtained. With slight interruptions the case progressed favorably, and recovery was complete at the end of a few weeks. The tumor, which was found to be a lympho-sarcoma, had involved between six and seven inches of the bowel.

M. Nicaise said that he was not in favor of subjecting patients, already weakened by disease, to a prolonged fast. If it was desirable to have the bowel empty, he prohibited the use of solid food, but allowed the yolk of egg and peptones, which were easy of digestion and left no residue in the intestine.

M. Pozzi said that he had once assisted Billroth, in an operation very similar to the one just described, in which that surgeon inserted forty-two sutures in the intestine, besides a few more in the mesentery.

M. Trélat did not approve of a great number of sutures in intestinal wounds, and used only as many as were absolutely necessary for perfect occlusion.

M. Bouilly said that he was also opposed to the employment of such an unreasonable number of sutures, which answered no useful purpose, but only created the danger of extensive sphacelus of the intestine. He inserted as many sutures as were necessary to secure perfect apposition, but beyond that every additional thread was a potential cause of failure in the operation.

M. Reclus then read a paper on

SPERMATOGENESIS,

and its relation to the radical cure of hydrocele. It had been asserted by Gosselin that spermatozoa were no longer produced when the cavity of the tunica vaginalis was obliterated. This assertion, the speaker contended, was erroneous. He had examined three hundred testes, and had found the tunica vaginalis adherent in twenty-four cases. In twelve cases the adhesions were only partial, and in these he had found spermatozoa in the testicles in eight. In the twelve cases of total adhesion, he had found spermatozoa absent in only three, and these three were in individuals aged, respectively, seventy, eighty, and eighty-four years, at which ages the spermatozoa might be expected to be absent in default of any lesion whatever. He thought that

ASPERMIA

was dependent, not on adhesion of the tunica vaginalis, but rather upon primary changes in the epididymis. The relation of hydrocele to affections of the epididymis was now well established, and adhesions of the tunica vaginalis were dependent upon the same cause, being consecutive in many cases to lesions of the epididymis. He thought it more logical, therefore, to refer the absence of spermatozoa to the primary alterations in this organ rather than to the secondary obliteration of the cavity of the tunica vaginalis. As a consequence of this belief he did not fear that any evil results would follow the obliteration of this cavity in the radical cure of hydrocele. All that was necessary to avoid was a wound or inflammation of the epididymis. He looked with less favor on iodine injections, which he thought were very apt to excite inflammatory reaction.

M. Monod asked whether the author of the paper had examined the testes microscopically. It had been shown that the gland was often altered in chronic vaginalitis and hæmatocele, a true sclerosis of the organ resulting in such cases. He thought these changes were of very frequent occurrence, and resembled the condition described by Gosselin under the name of testicular anæmia. Possibly the absence of spermatozoa in cases of vaginalitis, that is, of adherent tunica vaginalis, might be explained by the existence of this sclerosis of the testicle.

M. Trélat did not think it was possible yet to determine, with any approach to certainty, which of the two methods of treatment was the more likely to be followed by epididymitis. He had not often practised

THE RADICAL CURE OF HYDROCELE,

and consequently could not speak from an extensive experience, but he did not believe that, when strict antisepsis was enforced, there was any danger of inflammation following it. He had, however, made a considerable number of iodine injections, and he had never seen epididymitis excited by them.

M. Reclus said that it had fallen to his lot to see a very appreciable enlargement of the epididymis and other signs of reaction in almost every case in which he had injected iodine, whereas he had never seen any inflammatory manifestations after excision of the sac. He believed that sclerosis of the testicle was ordinarily secondary to a similar change in the epididymis. The gland was so shut off from the cavity of the tunica vaginalis by the albuginea, that it seemed hardly possible for a sclerosing process originating in the serous investment to invade it.

M. Terrillon said that the relation between diseases of the epididymis and those of the tunica vaginalis was well recognized, and it had frequently been demonstrated experimentally that the testis became involved only secondarily in the morbid process. In some experiments made several years ago, M. Schwartz and the speaker had proven conclusively that, when the epididymis was the seat of disease, the serous covering was always inflamed.

M. Trelat said that the idea of a close relation between diseases of the tunica vaginalis and those of the epididymis was no novelty, for he had heard Nelaton affirm his belief in it. It was, however, become more and more established as a fact every day. It was beginning to be seen that hydrocele bore the same relation to disease of the epididymis that dropsies of other serous cavities, notably the synovial, did to affections of the tissues and organs invested by them.

M. Reclus said that he had not gone into the literature of the subject, which dated back to the days of Percival Pott, as the object of the paper was not primarily to discuss the pathological relations of the testis to its sheath, but rather to speak of one etiological factor in aspermia and the means of its prevention.

The Society then adjourned.

A Western Editor on Gynecologists.—The editor of the *Pacific Medical Record* says: "It is safe to say that more than half the revenue of the physicians of the world is derived from the treatment of females; and if we say that nine-tenths of the number thus treated have no need of that treatment, and that it works actual harm, we shall utter the truth."

HOSPITALS MEDICAL SOCIETY OF PARIS.

Stated Meeting, July 13, 1888.

(Special Report for The Medical Record.)

M. Siredey, President, in the Chair.

M. Bucquoy, referring to a case reported at the previous meeting, of

LINEÆ ALBICANTES IN TYPHOID FEVER,

in which the cause was thought to reside in the rapid growth of the body during convalescence, said that such an explanation would not answer for all cases. He had recently seen two cases in which they were formed while the disease was still in progress. In one instance, occurring in a young woman, eighteen years of age, he noticed these lines just above the mammæ and along the iliac crests on the sixteenth day of the disease.

M. Barié showed some pieces of skin, removed from near the ankle, in which the atrophic lines were well marked. They were taken from a young girl who had died of typhlitis complicating typhoid fever.

M. Hayem read a paper on the

DIAGNOSIS OF HÆMOGLOBINURIA.

His paper was based upon a case which had been reported to the Society by M. Millard, as one of paroxysmal hæmoglobinuria. The patient, a woman, thirty-two years of age, had since come under his care, and he had been led to reject the previous diagnosis. On the day that the woman came into his service she passed red-colored urine, but the microscope showed the presence of red blood-corpuscles, and spectroscopic examination gave two faint bands of oxyhæmoglobine and one of urobiline, but the bands of methæmoglobine and of hæmatine were absent. The urine contained albumin, but not constantly, it being most abundant during the menstrual periods. The blood was present for one day only, and though the patient was exposed to the action of cold in order to produce it, it did reappear; but the albumin was always found in greater quantity after such exposure. The woman complained of pain in the left lumbar region, and she had cold sensations, horripilation, and cyanosis in the extremities, chiefly on the left side. The author concluded that there was some affection of the left kidney, and thought, first, that it was tuberculosis. Under the influence of a tonic treatment the patient's condition improved somewhat, but as she complained frequently of headache, was losing her hair, and presented some crusts on the scalp, he finally arrived at a diagnosis of

RENAL SYPHILIS,

and instituted treatment accordingly. Under the administration of mercury and iodide of potassium the headaches and other pains were speedily relieved, and soon all signs of the renal affection disappeared. From this he concluded that the case was really one of renal syphilis accompanied by paroxysmal albuminuria and hæmaturia. M. Millard had not found any blood-corpuscles in the urine, and had, therefore, made the diagnosis of hæmoglobinuria, but the course of the disease, even at its commencement, was not characteristic of this affection. The urine was of a brownish red color for an entire week, but the attacks of

PAROXYSMAL HÆMOGLOBINURIA

do not last for so long a time, disappearing usually within a few hours. The color of the urine varies also, passing from a light-red to, at times, even a deep coffee-color, and then growing gradually lighter again; but it remains clear and translucent, even while deeply colored. It never contains any red blood-corpuscles, and albuminuria in the intervals of the attacks is of rare occurrence. In the spectroscope, in addition to the two bands of oxyhæmoglobine, there is another band in the red portion which is due to the partial transformation of the hæmoglobine into methæmoglobine. In hæmaturia the urine is redder and is murky, and when first passed never shows the methæmoglobine band in the spectroscope. In acid urine, however, which has stood for some time, this band may appear, and the fluid becomes translucent, the blood-globules being decolorized and sinking to the bottom. In such a case it will be necessary to examine the sediment, treated with a drop of solution of iodine, under the microscope. The lumbar pains are seldom present in hæmoglobinuria. And in this affection, furthermore, the attacks are usually readily provoked by an exposure to cold.

A point of some interest which the author had observed in this case was that the blood-serum, in repeated examinations, was always found to be of a cherry-red color, and this was observed even after the patient's recovery. This would appear to overthrow the assertion made by some, that the coloration of the blood-serum was characteristic of hæmoglobinuria. He had also noted the presence of red serum (*sérum laqué*) in a patient suffering from subacute nephritis, and again, in one with heart disease and secondary hepatic congestion.

In conclusion, M. Hayem said that renal syphilis would seem to manifest itself in two ways—in a paroxysmal hæmoglobinuria and in an intermittent albuminuria accompanied by hæmaturia. In either case cold and fatigue are the exciting causes of the attack. In both forms, also, there are vaso-motor disturbances.

M. Millard was not at all certain of the existence of syphilis in this case. The only signs pointing to it were the crusts on the scalp, with the consequent loosening of the hair, and the headache, and this would seem to be a rather weak foundation upon which to base a diagnosis of syphilis. Furthermore, the patient was inclined to exaggerate all her sufferings, and it was not improbable that the cephalalgia was simulated.

M. Hayem said that he was not positive of the existence of syphilis in this patient, but it seemed fair to assume its presence in view of the fact that a cure was obtained by anti-syphilitic treatment.

M. Hudelo presented, in behalf of M. Troisier, a heart showing a

STENOSIS OF THE LEFT CORONARY ARTERY.

The patient was a man, fifty-two years of age, addicted to the immoderate use of alcohol and tobacco, who had acquired syphilis at the age of thirty-two. He was admitted to hospital for treatment of angina pectoris, from which he had been suffering for six months. The attacks were at first mild and infrequent, but soon began to appear at shorter and shorter intervals, and became atrocious in severity. No relief was obtained from treatment, and the patient finally died in one attack about two months after entering the hospital. At the autopsy the aorta was found thickened with patches here and there of hyaline material, which had not undergone atheromatous degeneration. Under the microscope there was seen complete perivascular sclerosis, which seemed to have had its origin around the small vessels of the external tunic. There was coronaritis, most marked in the left coronary artery. The wall of the vessel was thickened and partly calcified, its lumen being reduced to less than one-half its normal size, and the orifice of the artery was almost entirely occluded.

M. Huchard reported a case of

ANGINA PECTORIS,

occurring in a dressmaker, fifty-seven years of age. The attacks were of the pseudo-gastralgic form, the pain being located for the most part in the hypogastric region, and being excited by exertion or the taking of food. The pains were very similar to those of gastric ulcer, and, indeed, the case had been so diagnosed by another physician. Auscultation revealed stenosis and insufficiency of the aortic valves, and soon all the signs of a subacute aortitis became manifest. The speaker insisted that the diagnosis of angina pectoris should rest less on the seat of the paroxysmal pain than on the presence of an excessive arterial tension, and of the exaggerated diastolic bruit. The pain is not what is to be feared and combated, but it is to the reduction of the arterial tension that the therapeutic measures must be directed. The remedies proper for these cases are the nitrites and the iodides, continued for long periods, together with a milk diet. In this case some improvement seemed to follow the exhibition of iodide of sodium, but the patient finally died in one of the paroxysms. The autopsy revealed an obliteration of the orifice of the left coronary artery and dilatation of the right artery. The aortic valve was narrowed and incompetent, and there was also cardiac sclerosis.

M. Barie reported a case of angina pectoris in which the lesions of

GENERALIZED ARTERIO-SCLEROSIS

were found at the autopsy. There was a double aortic lesion, as in the case previously reported. One coronary artery was normal, but the other was dilated in the first part of its course, but at a distance of about half an inch from its origin became narrowed, and for the rest of its course was so small that it would not admit a hair.

M. Huchard presented a woman, thirty-six years of age, who had a

CONGENITAL ECTOCARDIA.

The heart was seen beating in the epigastric region, where it lay directly beneath the integument, the abdominal muscles being deficient at this point. The auricles and ventricles could be distinctly seen contracting alternately, and the heart could be grasped in the hand. The cardiac sounds were normal. It was a curious fact that the pulsations were more distinct at a point slightly above the actual position of the heart. Below the organ was a protrusion in the abdominal wall, due probably to a hernia of the stomach. There had been an arrest of development of the lower part of the sternum and of the adjacent portion of the abdominal muscles. The woman was married, and had had four children. She had suffered no inconvenience from the cardiac hernia until after her fourth confinement, when the projection of the organ became more marked, and she began to suffer from frequent attacks of vertigo. The speaker proposed to have constructed a shield to protect the heart, and at the same time to act as a truss for the hernia of the stomach.

The meeting was then adjourned.

The Treatment of Chronic Diarrhœa.—A correspondent of the *Medical News* sends the following prescription: "Many years ago I suffered severely from that trouble; I considered it incurable. Being in Paris, one of the best physicians there assured me that it could be cured by a diet of racahout, and it was. Afterward I found one could not get the acorn meal that forms the active part, but knowing that its usefulness must depend on the tannin it contains, I tried substituting for it the following:

Powdered chocolate, pure	½ lb.
Rice flour	½ "
Powdered sugar	¼ "
Tannin	¼ oz. (120 grs.)

The tannin, or the rest, separately, have little effect. Together they restore the tone of the alimentary canal and nourish as well as cure. One thing is essential, that is long cooking, not less than half an hour. If simply boiled a few minutes, the harsh taste of the tannin is very strong; with a good half hour's cooking that disappears wholly. It is impossible to distinguish the medicine from ordinary broma. I think this has something to do with its curative powers and with the ease of digestion by the most irritable stomach. The remedy is too valuable not to be more widely known. The amount to be taken is a teacupful morning and evening at meals."

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE CROONIAN LECTURES ON ANTIPYRETICS—ANTIPYRINE AND ITS MODE OF ACTION—COLD BATHING AND ITS VALUE—THE COLLEGE OF SURGEONS—DIPLOMAS IN PUBLIC HEALTH AND MEDICAL OFFICERS OF HEALTH—THE BRITISH LARYNGOLOGICAL SOCIETY.

LONDON, July 21, 1888.

IN Dr. Macalister's third Croonian lecture, at the College of Physicians, he pointed out that the height of the temperature was not always in proportion to the gravity of the disease in febrile affections. High maxima occurred frequently in mild cases, and low maxima in fatal cases. Such considerations forced us to consider the other factor in these diseases, viz., the infection. It was obvious that if the grave morbid phenomena could not be set down to the pyrexial temperature, we must attribute them in large measure to the action of the specific virus or poison. It had been shown by experiments that some, at least, of the textural changes which were thought to be most undoubtedly induced by heat were capable of being produced by infective causes, both in animals and in men. The granular or fatty change in the muscles, and particularly in the heart, was especially referred to. Turning to the question of treatment, it was pointed out that as the chief pathogenic factor in the specific fevers was apparently the specific virus, our first object of search must be for a specific remedy capable of destroying or counteracting the virus. Quinine in malarial fever, salicylic acid and its congeners in rheumatic fever, were of this nature, and their claim to be antipyretics rested largely on their specific action. The action of antipyrine was then considered in detail. Among other actions, it was shown from the data of an actual experiment that a full dose had a marked effect in increasing the rate of radiation from the unexposed skin, as measured by Masje with Eichhorst's radiometer.

In his fourth lecture Dr. Macalister continued the discussion of the action of antipyrine. It had been shown, he said, that in cases of typhoid fever the effect of antipyrine had been to diminish the total excretion of nitrogen from fifteen to thirty per cent. It also had an effect upon the perspiration. Too much importance had been attributed to the production of sweating as a thermolytic process. In certain cases of phthisis, with colliquative sweating, the lecturer had seen antipyrine lower the hectic temperature, and at the same time check the sweats, to the great comfort of the patients. Summing up its various actions, Dr. Macalister said that it appeared that antipyrine increased skin-radiation, diminished the difference between peripheral and central temperature, lowered the temperature as a whole, diminished thermogenesis, lessened the production of nitrogenous waste, and therefore nitrogenous metabolism, and frequently, but not always, increased perspiration, while it generally slowed the heart and slightly increased the tension of the radial artery.

In the fifth and concluding lecture the physiological action of antipyrine was further considered. The lecturer referred to its remarkable effect in allaying certain forms of pain, especially that which we are accustomed to call neuralgic. He concluded, from a review of all its properties, that antipyrine should be classed as a true antipyretic, and not merely as a refrigerant. It repressed thermogenesis, and at the same time did something to make thermolysis more efficient. It imitated nature; it produced an artificial crisis by the same mechanism that nature used in producing a true crisis. In neither case, however, was thermotaxis at once restored. As after a true crisis the temperature, though lowered, was still very unstable, so after antipyrine the temperature was ready to rise again on slight occasion, and did, in fact, rise as soon as the drug was eliminated. It did not cure the specific fever, it only allayed the pyrexia.

After briefly discussing the relative merits of antipyrine, thallin, antifebrine, and phenacetin, the lecturer went on to consider another antipyretic methed, viz., cold bathing. Though its application was originally based on a theory which he regarded as erroneous and one-sided—that high temperature is the primary source of danger in fever—the practice had, in typhoid fever at least, proved itself remarkably successful. Its action was considered at length and shown to differ from that of antipyrine. Cold bathing did not diminish thermogenic metabolism, and led to an increased discharge of nitrogen from the body. The two methods of treatment should be regarded as in a sense complementary, each effecting what the other did not. A combined treatment in which, for example, a cool bath in the evening procured a favorable night, while antipyrine kept the fever and its attendant discomfort within limits during the day, was an eminently rational one. It was certainly more practicable than the frequent cold bath, at least in private cases. As Riess had suggested, in the case of wasted, feeble, or aged patients, it would be an advantage to use an antipyretic which was proved capable of checking excessive metabolism, such as antipyrine; while in the case of robust and previously healthy patients the fact that cold bathing appeared to check metabolism, would not deter us from resorting to a mode of treatment which in typhoid had been abundantly proved to be beneficial.

The conservative party at the College of Surgeons have triumphed again—for the time. The supplementary charter has received the royal assent in spite of the vigorous opposition made to it. Within the Council, matters continue much as they were. Mr. Savory has been reelected to the presidency, and the coming year will be the fourth during which he has held the office.

The Local Government Bill now before the House of Commons has been the means of drawing attention to the value of diplomas in public health. Sir Lyon Playfair moved that in future (except under special circumstances) only the holders of such diplomas should be eligible for such appointments, and, with some modification, the principle has been accepted by the Government. It is to be wished that some change in the tenure of sanitary appointments could be made, for one able provincial medical officer of health (Dr. Hine, of Bradford) has been dismissed—or rather refused re-election—by his Town Council under circumstances amounting to a public scandal.

The newly established British Laryngological and Rhinological Society is not an unqualified success. I already hear rumors of an intention to conduct it in the interests of a clique, and I understand that several members have resigned, and that many others are likely to follow their example.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE INCREASE OF RABIES IN PARIS AND THE ANTI-RABIC TREATMENT—THE RATIONAL THERAPEUSIS OF PHTHISIS—THE PATHOLOGY AND TREATMENT OF ANGINA PECTORIS—CANCER OF THE ŒSOPHAGUS AND GASTROSTOMY.

PARIS, July 20, 1888.

IN a note in the *Journal d'Hygiène*, the editor begins by exclaiming that there is no longer any possible doubt as to the increasing augmentation of human rabies in Paris, and he founds his alarming statement on the announcement made by M. Pasteur, at a recent meeting of the Council of Hygiene, that, on the 19th of last June, sixteen persons bitten by mad dogs (eleven of whom at Paris) presented themselves at his laboratory to undergo the anti-rabic treatment. The eminent chemist hopes that the new measures adopted by the Prefect of Police, the object of which is to destroy all stray dogs, will diminish the number bitten. He cites the example of other countries where rabies has almost disappeared, owing to the rigorous measures adopted against dogs. Commenting on the above, the editor concludes that it would have been better to devote to the organization of a corps of men for this service some of the thousands of francs which have been fruitlessly expended in the construction of the Pasteur Institute, adding that we should not then have established this unfortunate coincidence : brilliant success of the method of anti-rabic inoculations, considerable increase of cases of human rabies ! At this same meeting of the Council of Hygiene, the President announced that several persons made a written application to the Prefect of Police, requesting him to ask M. Pasteur to furnish "indications and instructions on the first symptoms of rabies in dogs and cats." M. Pasteur, always faithful to the principles of exact science, replied that "it is impossible to define in an absolute manner the characteristic symptoms of rabies. Even the most expert men may sometimes make an erroneous diagnosis !" This is a sorry confession to make.

In the same number of the *Journal d'Hygiène* the editor draws attention to your interesting details on the opinions of German and American physicians of the city of New York, as recently published in THE MEDICAL RECORD, relative to the treatment of chronic affections of the chest (consumptives). He remarked that hospitalization and dispensaries having, till now, furnished only discouraging results, Dr. Dettweiller has established a sanatorium at Falkenstein accessible to all purses. In referring to the method of treatment so successfully carried out by Dr. Dettweiller, which essentially consists in the use of fresh air, liberal food, and alcohol, the writer recommends this method to the notice of the promoters of the League against tuberculosis. He then concludes his note by the assertion that these practical facts are worth as much, if not more, than the learned dissertations on the mode of the propagation of Koch's bacillus.

In illustration of the pathological anatomy of angina pectoris, Dr. Huchard, at a recent meeting of the Société Médicale des Hôpitaux, related the case of a woman, aged fifty-eight years, who was affected with angina pectoris. The examination of the heart established the existence of aortic stricture and insufficiency of action. Antipyrine and digitalis aggravated the state of this patient, who was only relieved by the employment of the iodide of potassium in large doses. As often happens in such cases, this patient died suddenly. At the autopsy was found a dystrophic sclerosis of the myocardium. There existed besides a dilatation of the aorta, a dilatation of the right coronary artery, and a stricture with obliteration of the left coronary artery. Dr. Huchard remarked that this case is interesting in more than one point of view. It is the one hundred and tenth case of angina pectoris in which was found, at the autopsy, a stricture with obliteration of one of the coronary arteries. It furnishes, besides, a remarkable example of what has been termed pseudo-gastralgic angina, which was exemplified in the patient under notice, as she had for a long time been considered to be affected with ulcer of the stomach, but at the autopsy this organ was found to be perfectly healthy. The author added that this case is also interesting in a therapeutic point of view, as it proved once more the efficacy of the iodide treatment, which he had for so long a time employed against angina pectoris. What creates the danger, observed Dr. Huchard, is not the pain, nor the paroxysm of angina pectoris in itself ; it is the ischæmia of the myocardium and arterial hypertension. To combat this ischæmia and this hypertension recourse must be had first to the iodides and to trinitrin afterward.

At the same meeting Dr. Troisier exhibited the heart of a patient, aged fifty-two, who had succumbed to a paroxysm of angina pectoris eight months after the commencement of the malady. This patient was at the same time a syphilitic subject, a great smoker, and much addicted to drink. The heart and the aorta were the seat of atheromatous lesions, the coronary arteries were equally atheromatous and contracted, principally that of the left side.

At a recent meeting of the Academy of Medicine, Dr. Nicaise communicated the case of a patient, aged seventy-five, who was affected with a cancer of the œsophagus, and who was condemned to succumb by inanition in a short time. Gastrostomy was performed, the stomach having been at once opened, which Dr. Nicaise said is preferable, particularly when one has to do with a patient very much enfeebled. Notwithstanding his advanced age this patient lived five months and ten days after the operation. During this lapse of time the fistula never presented the phenomena of irritation which are observed in other cases, and the matters had but little tendency to escape, which was doubtless owing to the opening being placed not far from the pylorus. This neighborhood should, therefore, be searched for in future operations. Dr. Nicaise here remarked that this case showed that gastrostomy should always be preferred to the œsophageal tube in the palliative treatment of cancer of the œsophagus, as with the tube one only remedies a part of the difficulty of alimentation. Moreover, the renewed attempts at catheterism irritate the cancer, the operation is often delicate, and the examples of false passages are far from being rare. Finally, one often meets with insurmountable strictures. Now that the antiseptic method is in vogue, gastrostomy constitutes an operation of little gravity in itself, and it insures an alimentation sufficient to enable one to prolong the life of the patient.

CHOLERA INFANTUM AND DIARRHŒA.

To the Editor of The Medical Record.

SIR : Dr. T. Clark Miller, in his interesting article in THE MEDICAL RECORD of July 21, 1888, entitled "Cholera Infantum and the Weather," says : "Under the head of cholera infantum it is becoming more and more the habit of physicians to group the diseases occurring in young children, during the season of high temperatures, which are characterized by impairment of digestion and assimilation and varying degrees of gastro-intestinal irritation." Although he thus seems to accept this grouping, in the remainder of the article he seems almost entirely to consider cholera infantum proper. Diarrhœa of young children bears nearly the same relations to high temperatures as cholera infantum, and is "characterized by impairment of digestion and assimilation and varying degrees of gastro-intestinal irritation," but it is a distinct and very different disease from cholera infantum in its symptoms, prognosis, and treatment.

In cholera infantum the great prostration, the anxious pinched facies, the dark coloring below the eyes, the lack of expression in the eyes, the mental hebetude, the retracted abdomen, the moist, cold, and often cyanotic surface, the very feeble pulse, and the great rapidity with which these symptoms come on, at once proclaim the disease to be something far more serious than "bowel complaint." The discharges from the bowel, also, are very different from those of diarrhœa, being of a character to indicate great depression of the circulatory and nervous systems, and they do not precede much, if any, the general symptoms. In diarrhœa the passages indicate a local irritation of the mucous membrane of the digestive tract, and frequently contain undigested food, especially in the beginning of the attack. General symptoms of prostration and weakness of circulation do not come on until after some time, in fact, not until the bowel trouble brings them on. The pulse is full, rapid, and, at first, strong, and the surface hot. Diarrhœa is sthenic, cholera infantum asthenic.

Their treatment also is essentially different. In diarrhœa the treatment is directed almost exclusively toward the condition of the bowel, and the greatest success is attained by the use of opium in large doses, bismuth, chalk, mineral acids, and pepsin, and when persistent of calomel, mercury-with-chalk, ipecac, and rhubarb.

With the exception of opium, these remedies do little or no good in cholera infantum. In this disease the opium must be given in very small doses as a sedative and food for the nervous system, but we have to depend, for the most part, upon supportive treatment, giving alcohol, digitalis, and camphor. Minute doses of corrosive sublimate seem to act well sometimes, but the most important measure is immediate change of air. Take them away at once, even if they must be carried on a pillow. Probably the best diet for them is cream and water, with a little brandy in it.

Many physicians do group these diseases together and treat them as varieties of one disease, but it is evident that this is a grave error, and I do not think it is becoming "more and more the habit" to do so, for I think that physicians everywhere are paying more attention to, and becoming more successful in, differential diagnosis.

D. E. English, M.D.

Millburn, N. J., July 28, 1888.

THE INFLUENCE OF THE CLIMATE OF FLORIDA ON CONSUMPTIVES.

To the Editor of The Medical Record.

Sir: In a letter, in the issue of July 14th, Dr. Drew criticises Dr. Knight's conclusions that "cases of advanced disease, with cavities or severe hectic symptoms, should remain at home. But sometimes the moist, warm climate of Florida is *beneficial*."

I think that Dr. Knight is quite correct in his view of the matter. He does not imply that the climate is *curative*; but I am sure that Dr. Drew and other physicians in active practice in Florida know from experience that, at least the discomforts of the condition are remarkably palliated by a residence in that climate.

Much of the suffering of the consumptive is due to bronchial irritation, pneumonic pains, and catarrhal annoyances, and these conditions, as Dr. Drew admits, are relieved by the climatic influences of Florida.

In my experience the lives of sufferers with advanced phthisis are rendered more tolerable by a residence in Florida than in any other climate with which I am familiar. If they do not, as the French have a way of saying, "die cured," they can at least exist in comparative comfort, and finally depart from this life with but little or no suffering. Pulmonary hemorrhage seems also to be less frequent in such cases, or is more moderate, than in Northern climates and in elevated regions generally.

In the large class of chronic cases of bronchitis, bronchial catarrh, and pneumonia, so prevalent in the North, and often mistaken for pulmonary tuberculosis, a winter residence in Florida is almost invariably curative.

These conditions, which are so frequently preliminary to tubercular deposits, are the ones that are particularly amenable to cure and prevention by that genial climate.

R. J. Levis, M.D.

Philadelphia, Pa.

A Disinfectant of Air.—According to M. Keldyche, who has just published the results of a series of experiments on the air drawn from hospital wards, air which has been saturated with eucalyptol will no longer give rise to colonies of bacilli in gelatine. The spores of fungi are able to pass unharmed, but as their action on the higher animals is probably limited, it is not a matter of much importance. If confirmed by independant observation this valuable quality renders the drug worthy of widespread employment, for no other disinfectant is known which can be relied upon to effect its purpose without rendering the air irrespirable, besides acting very injuriously on furniture, clothes, etc.—*Medical Press.*

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 5 to August 11, 1888.

Noerper, Egon A., Major and Surgeon. Relieved from duty at Fort Keogh, Mont., and ordered to duty at Fort Walla Walla, Wash. Ter. Par. 5, S. O. 175, A. G. O., July 30, 1888.

DeWitt, Calvin, Major and Surgeon. Relieved from duty at Fort Sully, Dak., and ordered to duty at Fort Missonla, Mont. Par. 5, S. O. 175, A. G. O., July 30, 1888.

Corson, Joseph H., Assistant Surgeon. Leave of absence extended one month. Par. 17, S. O. 178, A. G. O., August 2, 1888.

Harvey, Philip F., Captain and Assistant-Surgeon. Relieved from duty as assistant to the Attending Surgeon at Washington, D. C., and ordered to duty at Fort Keogh, Mont. Par. 5, S. O. 175, A. G. O., July 30, 1888.

Merrill, James C., Assistant Surgeon. Granted one month's leave of absence from August 3d. Par. 7, S. O. 178, A. G. O., August 2, 1888.

Gardiner, John de B. W., Assistant Surgeon. Will, on the expiration of his present sick leave of absence, report in person to the commanding officer at Fort Leavenworth, Kan., for duty. Par. 4, S. O. 178, A. G. O., August 2, 1888.

Gorgas, William C., Captain and Assistant Surgeon. Granted leave of absence for one month, to take effect on being relieved from duty at Fort Randall, Dak. Par. 4, S. O. 177, A. G. O., August 1, 1888.

Official List of Changes in the Medical Corps of the United States Navy for the week ending August 4, 1888.

Hudson, A., Medical Inspector. Detached from the Trenton, and ordered home.

White, C. H., Surgeon. Ordered to the Trenton, via Panama.

Urie, John F., Assistant Surgeon. Ordered to the Receiving Ship Franklin.

Bates, N. L., Medical Inspector. Detached from the Richmond, and to the Pensacola.

Anderson, Frank, Passed Assistant Surgeon. Detached from the Richmond, and to the Pensacola.

Kite, Isaac W., Assistant Surgeon. Detached from the Richmond, and to the Pensacola.

Jones, W. H., Surgeon. Detached from the Pensacola, and to the Richmond.

Stone, E. P., Assistant Surgeon. Detached from the Pensacola, and to the Richmond.

McCormick, A. M. D., Assistant Surgeon. Ordered to special duty in the Bureau of Medicine and Surgery.

Wieber, F. W. F., Assistant Surgeon. Reports arrival home, having been detached from Vandalia.

A New Substance for use in Local Refrigeration is Canadol, one of the constituents of a heavy naphtha-ether obtained by the fractional distillation of American naphtha. It represents a limpid, very volatile, easily inflammable fluid, possessing a strongly pronounced benzine odor (*Therap. Gaz.*). The liquid is insoluble either in water or in alcohol. It is used in the same way as the ether spray, but it is cheaper than ether.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 4, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	30	11
Scarlet fever	87	22
Cerebro-spinal meningitis	2	2
Measles	179	16
Diphtheria	108	27
Small-pox	0	0
Yellow fever	0	0
Cholera	0	0

Successful Partial Extirpation of Larynx.—Professor Billroth recently performed the operation of partial extirpation of the larynx and of one of the vocal cords on a patient suffering from cancer in the throat. Subsequently the man was brought into the professor's lecture-room, and after examination was pronounced "completely cured." He breathes quite easily without a cannula, and has a good appetite. It is, however, admitted that a relapse is almost certain.

An Impecunious Medical Student advertises thus in a Dublin paper: "Matrimony.—Young gentleman reading for the medical profession is desirous of making the acquaintance of a young lady; one with some means preferred; widow not objected to; all communications will be regarded as strictly confidential; enclose carte if convenient."

Infant Mortality.—The Italian statistician, Signor Bodie, has published some figures showing that ten per cent. of all infants in Europe die within the first month, twenty per cent. before the end of the first year, and thirty-three per cent. of the remainder during the first five years. Hardly seven children out of ten reach the completion of their sixth year.

A Natural Cubic Centimetre Measure.—Everyone has at his disposal a cavity, viz., the external auditory meatus, whose capacity is about a cubic centimetre. The right meatus holds a little more than the left, and the capacity increases slightly with the height. The exact average capacity in one hundred men, according to Hummel, is 1.06 c.c.

The Favorite Treatment of Pneumonia in the Pennsylvania Hospital is by the administration of quinine, ten or twelve grains daily, in combination with tincture of digitalis, nitrate of potassium, and whiskey.—*College and Clinical Record.* Some will probably think that this kind of treatment is a pretty poor one.

Cancer and Vegetarianism.—Surgeon-Major Hendley, Resident Surgeon at Jeypore, writes to the *British Medical Journal* of April 7, 1888: "M. Reclus has shown that cancer was all but unknown among the persons whose food was exclusively vegetable." "M. Verneuil also believed that the increase of cancer was largely due to the carnivorous habits of diet of the present generation." The records of the Mayo Hospital at Jeypore, which is under my charge, show no such immunity of vegetarians from cancer. From January, 1880, to the present date, one hundred and two major operations have been performed in the hospital in cases of cancer. Of these, forty-one were on the persons of meat-eaters and sixty-one on those of strict vegetarians who had never eaten meat since their birth. In India, where caste rules are exceedingly rigid, the fact that the latter were true vegetarians is capable of absolute proof. Among them are six Saraogis, a class of Jains who even reject many kinds of vegetables. Three of these Saraogis suffered from cancer of the breast. Out of one hundred and two cases there were three deaths attributable to the operation. There is no information available as to recurrence, or the contrary. The cases were divided as follows: Cancer of breast, 20; tongue or lips, 8; head and face, 17; upper extremity, 11; lower extremity, 8; trunk, 18; penis, 15; labia, 1; testicle, 1; glands, 3. There were sixty-two males and forty females, a large proportion of the latter in a country where the *purdah* system is in force. The maximum age was seventy years, the minimum eighteen years, the average forty-three years.

Sweating in Infectious Diseases.—In a paper read before the R. Accademia Medica di Genova on May 28th, Professor G. B. Queirolo expressed the belief that the ancient traditional treatment of acute fevers by diaphoresis was too much neglected at the present day. He was convinced that there was a considerable amount of truth in the old notion that the "peccant matter"—or "morbid virus," to give it its modern name—is, to a certain extent, eliminated in the sweat. He had been led to this conclusion by the results of some experiments on rabbits, which he inoculated with the sweat of patients suffering from various fevers (small-pox, ague, articular rheumatism, pneumonia, etc.). These experiments were controlled by others in which sweat from persons in perfect health was used in a similar manner. The sweat was always collected and kept under the same conditions, the reaction being neutral, and the specific gravity about 1.006. All the rabbits into which sufficient doses of "pyrexial" secretion were injected died in from two to forty-eight hours; while the others, into which an equal or larger amount of healthy sweat was injected, were not affected in any way whatever. The former died without showing any rise of temperature, and on *post-mortem* examination not one of the known signs of septic infection was discovered; the spleen was not enlarged, and only in a few cases was there some scanty serous or sero-sanguinolent effusion in the peritoneal cavity. Professor Queirolo thinks that these experiments prove that the sweat of persons suffering from infectious diseases contains toxic matters, as to the nature of which, however, he is not prepared to express any definite opinion. He urges that in such cases diaphoresis should be encouraged by every means in our power, particularly by making the patients drink large quantities of liquid, whereby the poisonous matters produced by the infecting virus may be, as it were, washed out of the organism. Dr. Queirolo is continuing his researches on this subject, and promises to publish his results at an early date.—*The British Medical Journal.*

The Composition of Certain Artificial Foods.—No one more than physicians should know the composition of the many artificial foods which are pressed upon their attention by enterprising commercial firms. The *Boston Medical and Surgical Journal* contains an article upon this subject by Dr. B. F. Davenport, giving analyses of some of these foods. One of these is Loeflund's Cream Emulsion, of which the composition is found to be as follows:

	Per cent.
Water	24.32
Fats	15.32
Soluble albuminoids	2.24
Insoluble albuminoids	4.99
Maltose and lactose	43.16
Dextrine	6.27
Ash	2.60

This agrees quite well with the advertised formula. But what is more remarkable, it has over twice as much butter fat as is claimed for it, while usually such preparations contain less than a fair whole milk would naturally yield. It does not dissolve readily in water, white curds separating and coming to the top. It is much too sweet to resemble cow's milk. Such an excess of saccharine matter is highly objectionable.

Wells & Richardson's Lactated Food.—The name of this food conveys a false impression, for it does not contain any milk. The claim that it contains fifteen per cent. of malt diastase, retaining its full activity, is not sustained by the analysis, where no diastasic action upon the over one-third-part starch was found when the food was brought into solution. In the presence of so large an excess of alkali no such action is to be expected. Its albuminoids are derived from the gluten, etc., of the cereal, and not from milk.

Composition.

	As advertised. Per cent.	As found. Per cent.
Water	....	7.76
Fat	....	1.64
Milk-sugar	25.00	29.65
Malto-diastase	15.00	....
Soluble carbo-hydrates	41.67	39.00
Starch	....	36.43
Gluten and soluble albuminoids	16.35	....
Albuminoids	....	11.85
Potassium bicarbonate	1.25	....
Phosphates	0.25	....
Sodium chloride and other salts	0.48	....
Ash	....	2.61

Malted Milk—Composition.

	Per cent.
Water	2.18
Fat	5.30
Albuminoid	16.88
Soluble carbo-hydrates	66.99
Starch	5.57
Malt-sugar and milk-sugar	50.40
Ash	3.13

This food differs from Nestle's and others like it in that most of the starch has been converted by malt diastase into maltose. The malt extract in the food as sold has no diastatic activity. The claim that the caseine has been predigested by the diastase, that is, converted into a soluble form, is not found to be true. The caseine in the "Malted Milk" is present, with its properties no more changed than they are in Nestle's, the Anglo-Swiss, Carnrick's Soluble Food, or other similar milk foods, prepared by evaporating down baked wheat powder with condensed milk. In all of these it is left behind as separate, hard, unchanged particles of caseine.

Reed & Carnrick's Liquid Peptonoids—Composition.

	Per cent.
Water	64.694
Alcohol	15.136
Albuminoids	2.021
Fat	0.031
Carbo-hydrates, mostly sugars	17.666
Ash	0.350

This claims to be "concentrated beef and milk with gluten perfectly digested." It is a strongly alcoholic liquid of a light yellow color, with an alcoholic burning taste, and with a smell similar to that of many preparations of hair-oil. It appears that the insidious introduction into the bed-room of an invalid, of a preparation claiming, as this does, to be of a highly nutritious character, and yet which is principally composed of alcohol, is a criminal act.

VON MOSETIG-MOORHOF, at the December 5, 1887, meeting of the Wiener Med. Doctoren Collegium (*Deutsch Med. Woch.*, 1888, p. 153), was original in one respect—his English. He quoted the following as Lister's own statement of his "fundamental satze :" 1. "Let the Wound to be Alone." 2. "Let the Wound to be protected." 3. "Let to the Wound her free discharge." The use of a foreign language in a medical society discussion is generally an objectionable affectation, but the procedure becomes doubly objectionable and indefensible when the philologist murders the language after Moorhof's fashion.—*Medical Standard.*

INTRATRACHEAL CARCINOMA WITH CANCER OF THE THYROID.—At a late meeting of the Pathological Society (*The Lancet*), Dr. Semon related a case of intratracheal carcinoma continuous with carcinoma of the thyroid. The patient was a man aged thirty-nine, under the care of Dr. Ord, and afterward of Dr. Sharkey, in St. Thomas's Hospital. The chief symptoms were hæmoptysis of some standing, emaciation, cough, and night-sweats. There was paralysis of the right vocal cord, with indistinct pulmonary symptoms. Locally there was some thickening external to the trachea low down, and laryngoscopic examination revealed what appeared to be tracheal ulceration just at the lowest border of the field of vision. All symptoms present in the case appeared compatible with the diagnosis of tubercular disease of the lungs and trachea, but no bacilli were found in the sputum; and toward the end of the patient's life Dr. Sharkey entertained a strong suspicion of malignant disease of the trachea. Death ensued from increasing hæmoptysis. At the post-mortem examination double pneumonia affecting the lower lobes was found. Examination of the organs of the neck showed a smooth ovoidal growth projecting into the trachea from the anterior aspect, about 1.5 ctm. below the lower border of the cricoid. Section showed an extensive submucous infiltration, the tumor substance spreading between the tracheal cartilages to the thyroid gland, and to the exterior of the trachea below the latter. The right recurrent laryngeal nerve was found to enter the mass of malignant disease which lay around the trachea. The histology of the growth was that of cylinder-celled carcinoma; the investing epithelium of the trachea was not involved. As the tumor was traced outward, its thyroidal character became plain. The cell-columns had everywhere a lumen, and were formed by a single cell-layer. This form of thyroidal carcinoma is very rare. Wölffler collected seven cases from different authors, and figured a specimen very like the present. It was also remarkable that the extension into the trachea took place in the form of a well-defined, comparatively large tumor, and not, as usual, of mere infiltration of the tracheal walls.

TANNIN IN THE TREATMENT OF TUBERCULAR DISEASE.—At the fifth meeting of the Societá Italiana di Chirurgia, recently held at Naples, Professor Ceccherelli drew attention to the value of tannin in the treatment of local affections of tubercular origin. (*The British Medical Journal.*) From experiments which he hâd made on animals, and from clinical experience, he believed it to be a powerful antiseptic, with a specific power of destroying the tubercular virus. He found that the addition of tannin prevented putrefaction of animal tissues and fluids, and that decomposition was very considerably delayed in the bodies of animals which, while alive, had undergone a course of treatment with tannin. He had also found that while he could produce tuberculosis in certain animals by the injection of phthisical sputa, or of tubercle bacilli, the injections produced no bad effect when tannin was injected simultaneously, or was given internally every day for some time. He had treated twenty patients suffering from tubercular diseases with tannin, both externally and internally, with very satisfactory results. He therefore looks upon tannin as an excellent remedy in tubercular affections of the bones and joints; under its influence ulcers heal kindly, any tubercular formations that may already exist are destroyed, and generalization of the disease is prevented. Dr. Ceccherelli considers that tannin is much superior to iodoform in the treatment of tubercular disease, besides having the further advantage of being perfectly harmless.

PROFESSOR JACCOUD recommends a copious diluent draught and an exclusive milk diet in the treatment of gout; in cases in which there is considerable fever he gives a small quantity of hydrate of bromal. Preparations of colchicine and of salicylate of soda, though excellent as anæsthetics, are to be avoided. In patients affected with interstitial nephritis these substances produce most serious toxic symptoms.—*British Medical Journal.*

THE EXTENSION-WINDLASS METHOD OF TREATING FRACTURES OF LONG BONES,

Especially Illustrated with Reference to Fracture in Upper Third of Femur.

By CHARLES DENISON, A.M., M.D.,

DENVER, COL.

For some time the writer has been under the impression that there is a decided opportunity for improvement in the mechanical management of certain fractures of long bones requiring extension. Special reference may be made to railroad, marine, or military surgery, or wherever the transportation of the injured to hospitals or their homes is necessitated.

Contrivances for producing extension in the treatment of fractures have been numerous and ingenious; but most of them have been cumbersome, uncomfortable, and not beyond question as to average results.

During his early hospital experience (1870) the writer devised the extension windlass, here illustrated (see Fig. 1), which he believed was the epitome of extension, or the concentration of that power into the smallest possible space for practical uses.[1]

This little instrument—about the size of an ordinary silver watch—can accomplish everything that may be desired in the way of extension, if properly applied. By this is meant, if it is suitably combined with plaster-of-Paris or silicate of soda bandage-dressing, felt splints, or other appropriate device. Furthermore, because it furnishes a fixed and definable power, it is by so much superior to all unstable or elastic methods of treating fractures requiring extension, heretofore the rule in surgery. It may be claimed that this is an intermittent force because it depends upon the intermittent acts of the attending surgeon. But the slight relaxation between the surgeon's visits is as nothing compared with the unstable conditions which have to be overcome alike by all methods of extension.

In the treatment of fracture of the femur by the pulley and weight, the varying amounts of shortening or lengthening, as you like it, on successive days, with the weight of traction unchanged, has somehow caused the suspicion in the mind of the writer that this *unstable force* (motion) tends to elongate or change those cells into fibrous tissue (non-union), which, in nature's reparative process, were intended to become *bone.* The extension by pulley and weight is considered unstable because it is only opposed by the more or less *flexible* resistance of muscles, tendons, and tissues. Such methods, typified in Buck's extension, are, then, unnatural, inhuman, and unreasonable, and must of necessity give way to the utilization of steadier forces to accomplish the needed extension. The beauty about the screw or windlass method is that it requires nothing further of resisting muscles once relaxed than simply to hold them in position, which is finally an extremely simple affair, when once they have succumbed to just sufficient extension.

Fracture of the neck or in the upper third of the femur.—One of the most difficult fractures to treat, in which the surgery of the day is not up to its average success in other directions, is intra- and extra-capsular fracture of the femur, or the two combined. If the ligamentum teres is severed, if the break is intra-capsular, or in old people, the pain or confinement involved, and the long time consumed in obtaining the possible shortening, non-union, or deformity, are satisfactory *only* because they seem heretofore to have been unavoidable. Even with less serious complications the rule of shortening is perhaps more liberal than it should be. This is a conclusion which, it is hoped, will be supported by the use of the extension windlasses suitably adjusted. There are two methods of application to be mentioned at present, one by the aid of plaster-of-Paris or silicate of soda bandage-dressing, and the other by porous felt-splint material, or a like substitute, properly cut and moulded to fit. The preparation for the first method consists, first, in the plaster-rolled bandages. These are to be applied over a thick pair of drawers, which can be pulled well up on the waist, or (with one to whom flannel may be irritating) silk or fine balbriggan drawers might be substituted, covered with cotton-wadding, canton, or lamb's-wool flannel, cut to fit a space

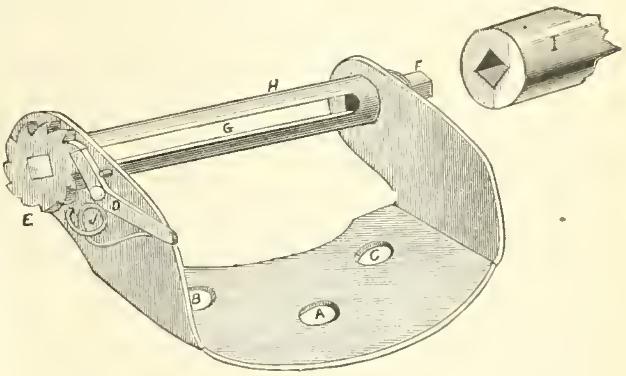

Fig. 1.—The Extension Windlass (diagram nearly the full size), made of brass, each pair of windlasses being rights and lefts, *i.e.*, the key-ends (F) of the winding-rod (H) both project forward on each side of the limb when in use. This winding-rod is firmly held in a bracket by means of which, through the perforations shown for screws or tacks, it is made either stationary (A, B, C) or swivel (A) upon any splint or wooden slat. The usual form of attachment (stationary) is to have the arms of the bracket, which are one and three-fourths inch apart, enclose the end of a pine- or soft wood slat of the same width. The windlass thus placed upon the outside of the slat, and the end of an adhesive plaster threaded through the slat at the winding-rod (G), traction is furnished about on a line with the surface of the limb to which the plaster is applied. The traction is regulated at will by the ratchet (E) and pinion (D) on one end of the winding-rod, the handle of the pinion serving as a means of throwing it off from the ratchet and thus letting up the tension whenever that is desired. The pinion is constantly held against the ratchet by the spring J, unless the handle of the former is purposely depressed. The winding-rod is easily turned by the key I.

---

[1] In making extension we cannot expect the muscular power to be overcome, and, at the same time, its relations to the various states of the nervous system to remain *constant;* and yet, with a weight of twenty pounds, a constant force, it is sought to overcome another which naturally weakens. While so great a power may be necessary at first, still, as the opposing power lessens, its influence is really proportionately intensified. In this contest with a man's muscle and nervous system, a bag of sand has undue advantage. Then, too, there may be some uncertainty as to the amount of extension used by the pulley and weight. Some surgeons habitually weigh the sand or material used, instead of guessing at it, and then endeavor to regulate this weight as the case may require. Such are probably the exceptions. Now, if the maximum weight required (as Professor Hamilton found in making extension for fracture of the shaft of the femur) is twenty-two pounds, who can give us even an approximate rule for the weight necessary on successive days after the injury, as muscular contraction is gradually weakened, or that would be applicable to the great variety of cases occurring? The nearest to a correct guide would be the *length of the limb;* but this is just as reliable in extension by the windlass, which requires no more of muscles once relaxed, than to keep them under control.—*New York Medical Journal*, May, 1875.

a little larger than that to be enclosed in the plaster bandage.[1]

Fan-shaped adhesive plasters are cut to fit the sides of the leg, reaching from the knee to below the foot, where they can be threaded through the winding-rod, being there one to one and a half inch wide.

Pine-slats are needed, one and three-fourths inch wide, one-fourth inch or less thick above, one-half inch thick below, long enough to reach from below the groin on the inside, and from the trochanter major on the outside of the limb to just below the arch of the foot or to the malleoli, as the surgeon prefers. The upper ends of these slats are thinned and roughened to favor fixation in the plaster bandage. To the lower ends of the slats the windlasses are attached; each windlass enclosing the outside of the end of each slat. It is desirable to spread the upward pressure of the plaster bandage over as large a surface as possible, and protect the perineum and gluteal region by fixing in this locality an absorbent cotton or similar pad—perhaps plaited—one-fourth inch thick, five inches wide, and two feet or more long. The turning outward of the upper edge of the bandage-dressing at this point also helps to make a broad impinging surface along the inner and upper border of the inverted and truncated cone, which will be the shape of the dressing as it fits the thigh. The perineal pad and protecting covering to the thigh and waist being in place, the patient is lifted up above the bed, or out from the bed and at a right angle to its side, and a chair is placed under the opposite hip to help support him in this horizontal position. The parts over which the plaster-of-Paris bandage is to be spread are then entirely free and the application can be quickly made, turning the broad bandages from the thigh around the waist by the figure-of-eight movement, and properly enclosing the roughened ends of the side-slats in the middle layer of the bandage.

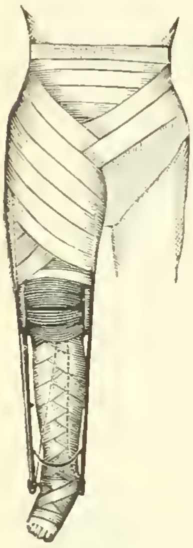

Fig. 2.

Extension had better be begun, by means of the windlass, before the bandage is entirely dry, so as to adjust the same to the swell of the thigh. Care should be also taken that the foot does not turn too much outward, that the thigh is slightly flexed upon the pelvis, and that the knee is a little bent, so as not to leave it in a strained condition. This latter can be accomplished by a broad band running from one slat to the other underneath the knee (see Fig. 2). The slats are held apart and prevented from pressing too much on the limb at their lower ends by a wire hoop extending over the limb and having sharp ends which stick into the inner surface of each splint, or pads may be tacked to the inner surface of each slat near their lower ends, which will guard the flesh from friction against the windlasses. In a variable time up to two days, after traction is commenced, the limb may be drawn down to the exact length of its fellow, and after that, for a week, turning the ratchet a chick or more a day, and the same amount every other day the second week, will probably be sufficient to hold the limb down in place, this being all that is requisite to neutralize the giving of the plasters and of the counter-extension around the thigh. If properly padded and adjusted, there is no pain from the upward pressure of the thigh-dressing. Care must be taken, however, not to use too much traction by the windlasses when once the muscles, etc., have succumbed to this apparently small, but yet invincible, force. How much better is this than the increasingly uncertain and never-ending traction on the pulley-and-weight principle of Buck's extension! The patient can be turned on to either side, and then be bolstered up in a comfortable way. Not only this, but with the aid of the nurse, who lifts the injured thigh and leg, the patient can move himself at will across the bed or on to a bed-pan. This is accomplished by the aid of the trapeze apparatus (illustrated in Fig. 3) which the writer devised for the use of his first case of fracture of the neck treated by this method. This the patient in question christened the "Fracture Alleviator," and was continually grateful for the comfort and freedom of motion which it afforded.

It consists mainly of a bar, which is made to swing down from a frame behind the head of the bed, so as to be within the reach of the patient, at which point it is made stationary by hinged supports, which fit into slats in the upright beams of this frame. The trapeze portion can be pulled up out of the way by a cord running over a pulley on the frame above. By this apparatus the patient lifts the thorax and head with the hands, and supports the body by the sound limb, while the nurse, resting his elbows on the bed, easily moves the disabled limb.[1]

The dressing of the leg and waist (Fig. 3) is intended to illustrate another, and perhaps better, method of treating these same fractures. It is a combination of a wide belt around the waist, made of four thicknesses of thick duck-cloth, attached to a porous felt casing to the thigh, to which, in turn, the side-splints are fastened either by copper rivets (used for belting), or better, by the slats being tied to the felting by tape threaded through holes punched in both. The felting is cut to fit the swell of the thigh (either of the patient or of another person of the same size) with a triangular projection on the upper edge and forward end, so as to form an extension of the dressing to and above the crest of the ilium. The writer has used the Russian felting, and been pleased with it. A paper pattern for this might be first made, which will have

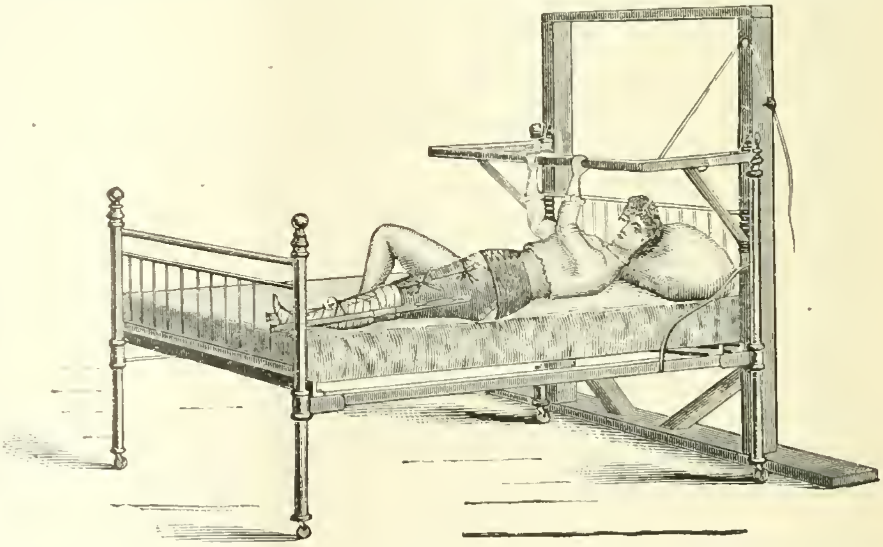

Fig. 3.

---

[1] If silicate of soda dressing is to be preferred (because it is lighter and less likely to crumble), a thick duck or tent cloth has lately been found by the writer to be best for the bandages.

[1] The silicate of soda bandage-dressing will have this advantage: It is lighter and can be cut open along the front of the thigh and abdomen; the cut edges can be bound and furnished with eyelets so as to be opened or laced up at will. The plaster-of-Paris, after much use, crumbles and irritates the patient, which the lighter bandage will not do.

the following shape and dimensions for a man six feet tall and weighing one hundred and sixty pounds :

Having been moulded to the required shape, and this upper border turned out and fastened or sewed down to the outside of the cone, the shell is set aside to become hardened. Through holes, punched in this casing with a shoemaker's awl, the broad abdominal belt is sewed to the same or tied by means of tape. This method is also found to be quite suited to attach the side-slats (thinned above) to the felting (see Fig. 3). When in use, the upward pressure of this casing is relieved by means of a generous pad of cotton rolled in cheese-cloth or other soft material, extending from over the gluteal fold to past the inguinal region. It may be well to suitably protect the thigh from this stiff covering, and also to secure to the cone, on its inner surface, long strips of padding, one just back of the trochanter major and shaft of the femur, and a smaller one just in front of the same, so as by their pressure to fix the bone in proper relation to the pelvis.

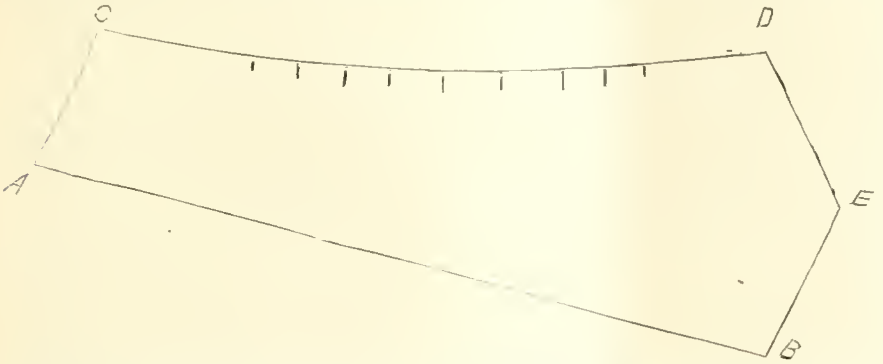

FIG. 4.—A B, distance around middle of thigh ; A C, or B E, distance from symphysis pubis to upper border of patella, about twelve inches ; B E D, about twice A C. For the right side, A C would be bent backward, and *vice versa* for the left side, A C lapping over B E, and the point D reaching above the crest of the ilium. After softening the felting the middle two-thirds of the upper edge C D is bent outward to form a rolling border, which process may be aided by slitting the edge one half to one inch deep, every two inches.

The advantages of this method of dressing the thigh and pelvis over the use of plaster-of-Paris bandage are its lightness, its adjustability through change in the padding, etc., and the facility with which the apparatus can be removed and the limb examined. At the same time, the control of the fracture and the conditions of suitable extension are as nearly perfect as possible.

It may be claimed that more ingenuity on the part of the surgeon is required to satisfy these conditions and adjust such an apparatus than to put up a limb by the old methods. Even if the claim is valid, it is so only in the first accurate adjustment. Afterward there is very little for the surgeon to do. It is hoped the plainness of the drawings, and the many details noted in these directions, may, in a measure, make up for any extra requirement of mechanical ingenuity. The results of this method of treatment of fracture of the cervix femoris in two cases where the first plan—that by plaster-of-Paris bandage-dressing—was used, have been most excellent, *i.e.*, with very little or no shortening. The first of these combined more unfavorable conditions than the knowledge or experience of the writer had ever presented, and the new method was not tried until the pulley and weight had been used and proved a failure.

The length of this paper does not permit of elaboration of other uses of the extension windlass. However, a brief mention of some of them will serve to indicate the wide range of uses to which the ingenious surgeon may put this little instrument, especially if he resides in the country or is away from depôts of surgical instruments where special appliances for extension are to be obtained.

A compound or comminuted fracture of tibia and fibula requiring extension is most admirably treated by the method illustrated in Fig. 5. The side-slats, like those already described, with windlasses on them, are simply inverted, and the thin and roughened ends are inclosed in the middle layer of an ordinary plaster-of-Paris dressing to the foot and leg. The dressing fits snugly only below the fracture, the foot being at right angles to the centre line of the leg. The pulling of the windlasses on the broad, fan-shaped adhesive plasters (bandaged to the thigh) simply pushes the dressing down to the required extension. In one case (comminuted) the tilting sideways of a four-inch fragment of the tibia was nicely prevented. In another case (compound and comminuted, 1874) the writer cut a large window in the plaster dressing over the tibia, where he had taken away half an ounce in fragments of that bone from its posterior surface. The remaining sharp points of the broken bones were so perfectly held in place that a good recovery was obtained with only one-fourth of an inch shortening. This was in a case where others had suggested amputation. With children, one windlass may be made to answer either for extension above or below the knee ; but with adults two are to be preferred usually. If desired, the windlasses can likewise be attached to the upper ends of slats fastened to the sides of an ordinary fracture-box, the foot being held to the foot-board by properly adjusted adhesive strips. The writer has always, by preference, slung these dressings in a coop.

Extension of the knee-joint can easily be imagined by duplicating the windlasses on the lower ends of the slats (shown in Fig. 5) and reversing the ends of the fan-shaped adhesive plasters to represent those which are applied below the knee. These side-slats need not be cumbersome, but must simply be strong enough to stand the required pressure at their ends, and not bulge too much outward.

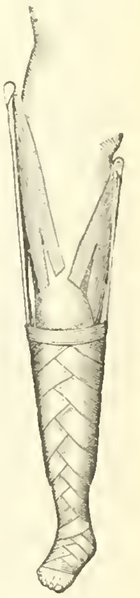

FIG. 5.

For extension of the ankle-joint (Fig. 6), notice how slats may be fastened to a foot-piece to which the foot is fastened by adhesive straps, and any desired angle of the foot to the leg be obtained by producing traction on either the posterior or anterior windlass (on the upper ends of the slats) as the case may require.

Extension of the hip-joint may be obtained by fastening the ends of a perineal band to the upper end of a long, light side-splint, over the lower end of which the extension windlass is made stationary. The fan-shaped adhesive strips are applied to the outside and back of the calf of the leg, converging toward the winding-rod. Or the point of traction could be reversed and two windlasses could be attached (swivel) to the upper end of the side-slat, or on a hip-piece to which this slat is jointed, each one pulling on separate ends of a long perineal band, while the lower end of the side-slat could be embedded in a plaster-of-Paris dressing to the leg; or it could terminate below in a right-angled metal brace fastened to the sole of the shoe under the instep. The perineal pad should have long ends and the inside of the upper end of the side-slat, or of an extra cross hip-piece if used, be properly padded, so that the traction of the windlasses would not produce uncomfortable pressure on the body.

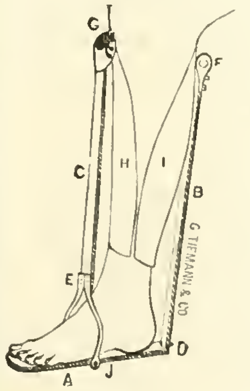

FIG. 6.

In 1870, while an interne in hospital, the writer contrived this windlass when treating his first case of fracture of the patella. He put the leg into a box made of half-inch pine-boards. Through the sides, which were higher than the limb, he put the round of a chair with a handle on its end, like the crank on a miner's derrick. The converging ends of adhesive straps, which wholly covered and controlled the quadriceps femoris, were threaded through a slat in this chair-round. The desired extension, thus obtained by turning the crank, was the chief factor in an excellent recovery with bony union. This led to the concentrating of this power of extension into the small space occupied by the windlass here illustrated. Fig. 7 shows this application on a finally perfected plan. However, the sides of the pine-splint should be raised a little higher than shown in the cut; the knee should be padded well underneath, so as not to be constrained in position, *i.e.*, not to be bent backward at that point, and the use of the limb, by the patient going around on crutches during the first part of the treatment (as was done with the case just mentioned) had better not be allowed.

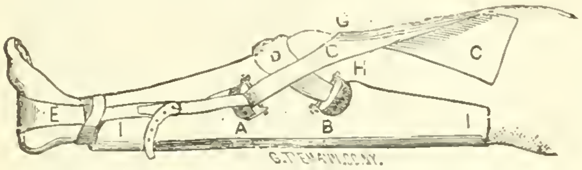

FIG. 7.—Fracture of Patella. A and B, extension and counter-extension windlasses, each fastened by one screw to the raised sides of a wooden posterior splint; C C are fan-shaped adhesive plasters crossing each other at G, and threaded through the winding-rods of A. D, a padded roller in front of ligamentum patellæ, the ends of which are threaded through winding-rods of B; E, reserve counter-extension to relieve D from uncomfortable pressure over the ligamentum patellæ. I I, points at which the posterior splint is bandaged to the limb. The bandaging of the limb, especially over the adhesive plasters, is not shown in this and the two preceding cuts. Brittain & Barber, of Denver, have made some dies to get these windlasses out cheaply; from whom, or from George Tiemann & Co., New York, they can be obtained quite reasonably.

A word in closing. It is with some apprehension that this paper is given to the press, because of the possible failure to appreciate the conditions necessary to a successful use of the instrument. It is surprising that a few physicians have at first seemed to experience difficulty in understanding where the extension and counter-extension are obtained, as shown in Figs. 2, 3, and 5. Then, again, too little, too thin, or too weak adhesive plaster might be used (a generous amount of Maw's moleskin, snugly applied without wrinkles, answers best); or the neglect to shave off the hairs where the plasters are to be applied; or to sufficiently protect by padding where much pressure is to be borne; or the mistake of leaving the joints in a constrained position; or of extending the limb longer than its fellow, any of these might lead to discomfort and so disparagement of the method. If, however, the requirements, as they are manifested, are appreciated, and reasonable ingenuity and patience are exercised in the adjustment, then this little instrument will prove itself a boon to others, as it has to the writer, in the treatment of some very difficult fractures of long bones.

April 27, 1888.

THE STATEMENT THAT WOMEN STUDIED MEDICINE IN IRELAND in the eighteenth century will doubtless surprise many physicians who have believed that the natives of that country entertain peculiarly restrictive views as to the position of the female sex, yet a stanza of Dr. J. Gilborne's poem, published in Dublin in 1775, refers to Dr. E. Foster, of Dublin, a noted eighteenth-century authority on obstetrics and hospitals, as follows:

> "Judicious Foster feels the latent Pulse,
> To hidden Maladies gives quick Repulse,
> In Parturition brings propitious Aid—
> Each Dame retrieves that has by him been laid.
> He teaches Pupils, either Sex, apart,
> In learned Lectures his mysterious Art."

—*Medical Standard.*

DISEASES OF THE SKIN DUE TO DEFECTIVE ALIMENTATION.

BY WILLIAM T. CORLETT, M.D., L.R.C.P. LOND.,
DERMATOLOGIST TO CHARITY AND ST. ALEXIS' HOSPITALS, ETC., CLEVELAND, O.

THE spirit of inquiry leads to analysis, while observation leads to synthesis. It is the latter that is receiving more attention at the hands of the profession at large than in time past. The crucible, the microscope, and the scalpel have each contributed to medical lore, and the torch of inquiry has even illuminated some of the dark and mysterious processes of growth and repair.

All agree that to maintain functional vigor there must be structural stability, and structural stability depends upon a proper supply of reconstructives; but in what form administered to supply the waning vitality of this or that structure we have only conjecture.

To clinical observation alone must we look for definite instruction.

In this line of thought let us trace the rôle which food plays in the healthful maintenance of the skin, as well as in those of its diseases which are dependent upon a disturbance of this great nutritive function.

In common with other organs, the corium requires a plentiful supply of oxygenated blood; but, in addition, certain substances are here called for to supply the hair-papilla, the matrix of the nail, and the rete mucosum at large with a corneous element as well as an albuminous cement—brick and mortar to house the ghastly mechanism of life with beauty.

Analysis teaches that these substances are most plentifully supplied from the outer strata of cereals. But a fine-haired civilization feeds only on the whitest flour and casts this bristle-forming material to the swine, until, if observation be not misleading, there is danger that man in his most civilized state will lose his grip on his congenital hirsute adornment. But here again we must appeal to observation.

There is no doubt that, aside from the abnormalities of growth, defective alimentation is a potent etiological factor in cutaneous pathology. In infancy it appears most frequently as an eczema, while later, urticaria and erythema are often met with. Of the former, Hardey[1] says that it often appears in infants from an insufficient supply of the nurse's milk; at other times the quality is at fault. It will also supervene upon too early weaning when the child is fed with a little of everything.

That infantile eczema is sometimes a sympathetic disturbance, due to an irritation of the gastro-intestinal tract, like erythema and urticaria, seems highly probable; that it is frequently dependent on an aberration of nutrition is more generally admitted. The first is not only highly probable, but it is true, as evidenced by clinical observation. The second is equally true, but it is viewed from two opposite stand-points. Thus the delicate skin of the infant in a state of malnutrition readily succumbs to irritating external agencies, which latter fulfils the requirements of the Vienna School of Dermatology, while the former supplies a *diathesis* to the French.

In adolescence, or between the extremes of life, the cutaneous affections arising from defective alimentation are, first, those in which assimilation and disassimilation are at fault; and, second, the neuroses.

In an address before the Medical Society of London[2] Sir Erasmus Wilson said: "Well, our first six patients are adults, say between forty and sixty years of age; some have eczema, moist and dry, recent and chronic; some erythema, some gutta rosea, and some lichen. We inquire into the functions of digestion and assimilation; in the majority we find symptoms of gastric disorder, nausea, loss of appetite, flatulence, distention, constipation, all more or less confirmed. Our pen flies to the paper; we are about to prescribe; and for what?—for indigestion and malassimilation. But our patient consults us for cutaneous disease, not for his stomach or liver or digestive organs, with which he finds no fault, and which he is not aware of being in a state of disorder; while we, on the other hand, know the assimilative organs to be the cause of the irritation, and that if they be restored to their healthy function all the cutaneous symptoms will subside and disappear. Undoubtedly, when the *force majeure* has been dealt with, we shall advise our patient as to some local treatment, an ointment, a powder, or a lotion for the immediate relief of the skin; but, practically, we treat the cutaneous affection as if it were altogether secondary in importance; neither need we care to inquire too minutely whether the anatomical lesion is an hyperæmia, a papule, a vesicle, a discharge, or a state of desquamation. And if we be in want of a name to include the cases of this description, we might adopt the word assimilation, and consider this as an *assimilative group* of diseases."

---

[1] Traité des Maladies de la Peau. Paris, 1886.

[2] On the Progress of Cutaneous Medicine during the present Century. London, 1876.

These were some of the last words of one of England's best-known modern dermatologists.

In addition to what has been said in a previous communication [1] there is no doubt that the large consumption of nitrogenized foods, such as lean meat, eggs, etc., is conducive to derangements of the skin in common with other excretory organs. Beer, too, often has a deleterious effect, as seen in the following cases:

Case I.—L. H——, butcher, aged fifty-four, complained of swelling of the face and arms, with a red, slightly moist, eruption, which was very itchy. He was seen, in consultation with Dr. Hausheer, in December, 1887. His previous health had been good, excepting a similar attack a year or two previously. He was in the habit of eating plentifully of meat, and of taking copious draughts of beer in the evening. At the time of examination he presented a robust appearance, with a dilatation of the superficial blood-vessels of the face. He had a moist eruption on the upper half of the body, with marked œdema, as before mentioned. He perspired freely at night, and emitted a distinct urinous odor from the skin. The urine was normal in quantity, of amber color, sp. gr. 1.028, acid, with a copious deposit of urates.

The treatment adopted was as follows: Diet restricted to light non-nitrogenized substances, as gruel, dry toast, and milk; hot water taken freely an hour before meals, and pilulæ hydrargyri followed by saline cathartics. This was supplanted by potassii acetas with diluents, which in turn were followed by vegetable bitters. The external management consisted of warm alkaline baths, the lotio evaporans of Hutchinson,[2] and, finally, glycerinum acidi tannici. The patient made a good recovery twenty-one days afterward.

Case II.—W. H——, dentist, aged thirty-five, of unsettled nervous temperament, sought advice for a moist itchy eruption on the upper part of the chest and neck; he never had been afflicted before in a similar way. To increase his weight, he had followed a system of generous diet, with a free supply of beer at night. At the time of examination the urine was normal, but the bowels were constipated. He was given a light diet, ordered to discontinue beer, and was advised to drink Hunyadi water before meals. He was under observation ten days and ended in recovery.

These cases would come under the general title of eczema. But do not understand me to say that eczema is always the result of malassimilation or defective disassimilation; on the contrary, its causes are divers, and their name is legion. Thus, eczema occurring in the neurasthenic from derangement of digestion often assumes the character of a reflex neurosis, as in the following:

Case III.—Mrs. J. V——, aged forty-two, complained of an eruption on the face and hands which was very itchy. The family history shows that her mother had an eruption on the face which was called erysipelas; she also had asthma, from which she died. The patient has two sisters, one of whom has a similar eruption, and the other suffers from neuralgia. Her previous condition has not been good, and since 1883 has had recurrent attacks of the eruption every spring. Her present condition is markedly neurasthenic, and her emotions are sometimes beyond her control. While detailing her symptoms she broke down with a fit of crying, and a few minutes after her spirits were as light as a miss of twenty. The eruption is bright red and slightly scaly, distributed around the mouth and parts adjacent; less marked on the dorsal surface of the hands. She has constipation alternating with diarrhœa. She says strawberries and tomatoes act like poison on the eruption.

With this state of affairs, it seemed an excellent opportunity to test the effect of certain articles of diet. Accordingly, she was restricted to oatmeal and milk—not on the theory of *similia similibus curantur*, for I believe oatmeal to be a most wholesome food in diseases of the skin. The same may be said of buckwheat flour. In addition to the diet she was given the lead-wash, and a pill containing one-eighth grain each of calomel and ipecac after meals. At the end of four days she was much better and the fiery redness had disappeared. Strawberries were now added to the diet-list, when the following observations were made: Half an hour after eating she complained of an uncomfortable sensation in the stomach, which soon passed away; two hours after eating, the affected parts of the skin began to tingle and itch, without any appreciable change in appearance.

After the second meal the same symptoms were complained of, and, three hours after eating, the skin became inflamed, with marked discomfort. It was found necessary to discontinue further investigations, but the patient assured me that tomatoes acted in the same way.

Case IV.—J. G——, drayman, aged forty-four, complained of an acute eczema of the face and neck. He had previously had asthma. He was doing well under a soothing course of treatment similar to the preceding, and seemed in a fair way to end in recovery, when his wife yielded to his craving for raw onions, which he ate freely.

The next day the face and neck were acutely inflamed, and the itching was greatly aggravated. This yielded to treatment as before. The case was also seen by Dr. G. C. Ashmun, the family attendant. There is no reasonable doubt that these articles of diet, which to most persons are wholesome, in these instances were instrumental in inducing a relapse.

Just what vital process is involved in producing a surface inflammation from certain substances acting primarily on the gastro-intestinal tract may be studied best from a synthetical stand-point—from observation.

He who has seen the flush of the *bon vivant* after a full meal, and has noticed, too, the ariæ involved in this glow of repletion, may more readily trace certain cutaneous derangements to their remote source. He may have more readily impressed on his mind, too, that the pathological is but a step in excess of the physiological, and that a knowledge of the latter leads to the development of etiology.

And so it is in many diseases of the skin which we cannot associate with local irritation, diathesis, or extraneous substance seeking exit from the blood. More rational is it to affirm that they are perverted reflex manifestations of a physiological function. In place, then, of the reflex centres transmitting the vaso-motor relaxation to the mucous membrane of the stomach, a part of this influence is diverted and appears on the surface of the body as an erythema, urticaria, acute eczema, or a prurigo.

Then, again, there are diseases of the skin which are caused by the withdrawal of the vegetable acids; scurvy is representative of this class. In the winter and spring of 1884 there occurred a number of cases of these scorbutic eruptions of the skin and mucous membranes in the Cleveland Workhouse and in a neighboring Bohemian settlement. Through the courtesy of Drs. Sawyer and Stevenson opportunity was given me to follow some of these cases. The most noteworthy symptoms were great prostration, pain and swelling of the joints of the extremities, with bullæ of various sizes filled with bloody serum. The teeth were loosened and the gums bled on the slightest provocation. Those whom I saw subsisted almost exclusively on bread, and on supplying a mixed diet with fresh meat and vegetables, the disease yielded without further serious consequences.

In the aged, derangements of the skin, associated with defective alimentation, have been most painfully apparent at the public services. Here we see nature unassisted by art sometimes grappling with a sinking vitality, sometimes keeping afloat without fuel to move the complex enginery of life, and without a guiding hand to direct its tottering course. At this epoch, too, the circle of life nears completion, the beginning and the end become blended as one, and the same obstacles arise that were encountered in infancy. Defective teeth allows solid food to pass into the stomach without having undergone the first process of digestion, and many who present themselves with an urticaria or an eczema have these millstones of the body entirely absent. To this special defect I wish to call attention as having escaped the careful observation which it deserves.

CASE V.—Mrs. A——, aged fifty five, had always enjoyed good health until eight months previously, when she was attacked with a cutaneous disturbance which prevented sleep. Upon examination no definite lesions of the skin could be made out except nail-marks. Dr. Phinney, of Newburgh, with whom the case was seen, had observed these paroxysms, which took place between 1 and 2 A.M., and which lasted until daybreak; the diagnosis was urticaria. This hale matron had lost her teeth about a year before, and was in the habit of eating heartily of meat, vegetables, and sometimes pastry, late in the evening. She was advised as to the nature of her discomforture and directed to a dentist; in the meantime to eat only soft food, such as soft-boiled eggs, porridge, and milk. A year after this the family medical attendant told me that the urticaria became less annoying and ceased after the patient became accustomed to masticate with artificial teeth.

CASE VI.—Mrs. R——, aged seventy-two, complained of eczema of twelve years' duration. Previous to this she had enjoyed good health. Her teeth began to decay at about the age of fifty, and ten years later she was compelled to have them removed. Since the eruption appeared she has been a faithful attendant at the different dispensaries, and entered my service in 1882, where she was treated without much benefit. Four years later she returned for treatment, saying the disease had become so distressing that without relief life would be unbearable. At this time I was more strongly impressed than before that defective mastication bore an important position in the etiology of the disease. In accordance with this, she was given the following diet list: Breakfast—Black tea, very weak, milk toast, oatmeal, cracked wheat, eggs poached or boiled (three minutes), boiled milk. Dinner, at noon—Beef-broth or bean-soup, broiled fresh fish, mashed potatoes (sparingly), turnips, squash, pudding, huckleberries, peaches, milk. Supper—Gruel, with milk, weak black tea, dipped toast with butter. She was directed to eat lightly and slowly. The previous line of treatment was resumed. The result was marked. At the end of seven weeks the eruption had entirely disappeared, and she, who supplied the text as a *typical case of eczema senilis* to so many succeeding generations of students, and who was a living, a suffering monument to the futility of our art, now embodies a text more potent than words, to the value of dietetics in the well-being and management of the skin. What, then, do these principles teach?

1. That man is an omnivorous feeder and cannot thrive on bread alone, neither can he maintain a healthy skin on an exclusive diet of meat.

2. Those having irritable skins should avoid the continual use of: *a*, In youth—rhubarb, the small seed fruits, apples, shell-fish, sugar and acids sparingly, malt liquors and spirits; *b*, in old age—lean meat, eggs, beans, shell-fish, pastries, malt liquors, and spirits.

3. That wholesome foods may become unwholesome: *a*, By improper cooking, as hot cakes, heavy puddings, etc.; *b*, by defective mastication, either by eating too rapidly, or from loss of the teeth.

TREATMENT OF CATARRHAL JAUNDICE.

By R. N. KITTRELL, M.D.,
GADSDEN, ALA.

WHEN only a single recovery can be adduced in support of a certain line of treatment there is usually some room for doubt, but when five cases occur of the same disease, all conducted to speedy recovery by the same therapeutic measures, there is just reason to believe that the remedial agents are efficacious, and that a true sequence of cause and effect exists.

As my cases are identical in every respect, I will discuss them collectively, for fear of wearying the reader by tiresome repetition. In each case there were frontal headache, an intensely yellow integument and conjunctivæ, a bitter taste in the mouth, and tongue covered with whitish fur. The bowels were, for the most part, constipated, and, if moved, the dejections were of a light color. The urine presented the appearance, as one of my patients graphically described it, of mustard and water.

The respirations were shallow, as more or less pain was usually produced by taking a full inspiration. The pulse varied from 40 to 65 beats per minute, owing to the sedative effect of bile upon the circulation. In all the cases there was slight pain and tenderness in the epigastrium and lower portion of the right hypochondriac region. This symptom led me to believe that there was subacute inflammation of the duodenum, and that the jaundice was due to absorption, caused by the obstruction of the ductus communis choleductus by mucus. An examination of the urine confirmed this opinion. By means of Pettenkofer's test I detected the presence of biliary acids in the urine, and thus clearly proved that the jaundice was due to the absorption and not to the suppression of bile, for, as is well known, the biliary acids are formed by the liver, and, if it had been a case of suppression of bile and the liver had struck work, no biliary acids would have been formed, and consequently their presence in the urine could not have been detected. On the other hand, in the case of absorption, bile is formed by the liver, but being dammed back upon the liver by an obstruction in the biliary passages, the biliary acids along with other constituents are taken up by the lymphatics and capillaries, are eliminated by the kidneys, and consequently can be detected in the urine by the proper tests. I fear that my readers will accuse me of being too prolix and didactic, but this is the mode of reasoning by which I arrived at my diagnosis, and they will pardon me for reproducing it on paper. Having settled the matter of diagnosis satisfactorily to myself, I next considered the treatment. In each case I employed a drachm of the phosphate of sodium three times a day, and externally an application to the right side of dilute nitro-muriatic acid. A flannel jacket was made, sufficiently large to cover the entire right side, and confined by tapes attached to the borders of the flannel cloth and tied under the left axilla. This flannel was worn constantly, and was kept saturated with the dilute acid. Under this treatment the longest time required for recovery was thirteen days, two cases recovered within a week's time, and two in about ten days. I attribute the good results in these cases principally to the phosphate of sodium, for one of my patients neglected to use the acid, and recovered promptly in about a week's time. I consider that I have attained very good results in the treatment of this affection, and, if any one can show better results from the employment of other remedies, I shall be glad to profit by his experience.

RECTAL INJECTIONS OF CARBONIC ACID IN THE TREATMENT OF VOMITING OF PREGNANCY.

By A. ROSE, M.D.,

NEW YORK.

A PERUSAL of the editorial note on "Hyperemesis Gravidarum," in THE MEDICAL RECORD of May 19, 1888, has led me to describe a remedy which suggested itself to me from theoretical reasons, and which I applied successfully. I feel the more justified to speak of this remedy as I found it, though in another form, published independently some time after my own first observations and experiences.

Early in the year 1884 I was called to Brooklyn as consulting physician in a case of incessant vomiting in pregnancy. The case appeared to be a very grave one, and many remedies, such as absolute rest and strict diet, had been employed in vain. I, for the first time, suggested introduction of carbonic acid gas into the vagina, and exhibited a simple apparatus to accomplish this purpose; I presented also to the attending physician a little paper which I just had published in the *Annals of Anatomy and Surgery*, December, 1883, entitled "Carbonic Acid Gas as a Local Application to Chronically Inflamed Mucous Surfaces."

My idea was to make use of the well-known anæsthetic effect of the gas on the womb, especially on the os, of which I had spoken in the quoted article. I assumed that the vomiting might be in this case reflex action, originating in neurosis of the womb. For some reason or another my suggestion was not accepted.

In my little paper mentioned, I spoke of my employment of carbonic acid gas in cases of impotency, and more especially of dysentery.

Wertheim ("Kohlensäure gegen Impotenz," *Wiener med. Jahrb.*, 1882, p. 10) had recommended the application of carbonic acid to the penis and scrotum, thus making use of certain physiological effects of the gas upon the epidermis in the treatment of impotency.

I soon found that inflation of the rectum with carbonic acid gas had a more decided stimulating effect on the sexual organs than its application to the external parts by means of a rubber bag charged with the gas, in which the penis and scrotum were encased. The absorption took place much quicker and more completely from the mucous membrane of the rectum than from the epidermis of the scrotum and penis.

The idea of introducing carbonic acid into the rectum instead of into the vagina, in case of incessant vomiting in pregnancy, the former organ offering better facilities for absorption, suggested itself to Dr. Adrian Schücking, of Pyrmont, Germany ("Zur Therapie des Vomitus Gravidarum," *Centralblatt für Gynecologie*, 1885, No. 12); his cases are the following:

A woman, aged thirty-eight, who had been pregnant four times without experiencing extra difficulties, and had always had easy deliveries, was in the fifth month of pregnancy, and had complained, ever since the first days of this state, of nausea and frequent vomiting. These symptoms did not lessen with the beginning of the second half of the pregnancy; on the contrary, they became considerably aggravated. When Dr. Schücking saw the patient in September, 1884, her condition had assumed a dangerous aspect; she was greatly emaciated and miserable, and could not even retain liquids on the stomach. The uterus and cervix were in a normal state. Dilatation of the latter did not have the desired effect in controlling the vomiting.

The attempts in the way of dieting and other hygienic measures, the usual medication, had brought no improvement. As the patient was sinking rapidly, Dr. Schücking proposed a remedy which he had already successfully employed in another case, a year previously.

This latter case was that of an unmarried lady suffering from tumor of the right ovary of the size of a child's head. There existed obstinate constipation (probably caused by pressure of the tumor on the intestinal tract), and violent vomiting after each meal. Neither ice nor cold drinks could be retained. The patient refused her consent to operation. Meanwhile she had become so enfeebled that she could not raise herself in bed without assistance. After all other remedies had been tried in vain, Dr. Schücking irrigated the rectum with carbonic acid water of the Pyrmont Spring, Helenenbrunnen, which had been warmed to blood heat. This water is highly charged with carbonic acid. Simple warm water introduced in the same way had had no effect on the vomiting. After the first applications of the carbonic acid water the vomiting ceased, and this remedy proved so beneficial that very soon all medication could be dispensed with.

In the case of the above-mentioned patient the application of Pyrmont carbonic acid water proved likewise gratifying. After about two quarts of carbonic acid water had been injected into the rectum, small quantities of water and wine, and very soon beef-tea, milk, and buttermilk could be retained. The patient's appearance, as well as her general condition, improved, but it was found necessary to continue the irrigations daily for six weeks.

In this case, as well as in the first, irrigations with simple warm water, which had been made for the purpose of comparison, had had no influence whatever on the vomiting.

The patient with ovarian tumor did not support the substitution of artificial Seltzer water, as it caused ructus and the sensation of violent pressure in the intestine; in the other case, however—that of the pregnant woman—the artificial Seltzer water acted nearly with the same effect as the natural Pyrmont carbonic acid water. It is probable, says Schücking, that the unequal distribution of carbonic acid in the so-called Seltzer water, and the development of large bubbles of gas, may have something to do with the different effect. Dr. Schücking assumes that the carbonic acid brought on the favorable result, either by its well-known anæsthetic effect, or its antiseptic action, and finally, perhaps, by the considerable dilatation of the intestine. In both his cases of incessant vomiting the condition of the patients had been such that a fatal issue would not have caused surprise.

I confined myself to inflation of the rectum with gas, and never applied the gaseous water in cases of vomiting in pregnancy. The results were invariably gratifying. I have never met another case of so-called incessant vomiting since the one above referred to, seen in consultation. Perhaps by my early applying the carbonic acid, graver symptoms may have been prevented in one or the other of those I attended.

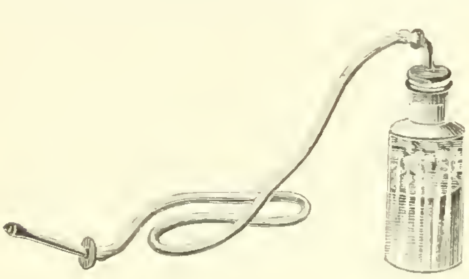
In certain forms of intestinal obstructions it has been recommended to make use of an ordinary siphon bottle containing carbonic acid water, to attach a rubber tube with a nozzle to the mouth of the bottle, turn the latter upside down, if we wish to introduce the test gas. This mode of procedure cannot be employed in case of pregnancy. No matter how gently we may press on the knob to discharge the gas, the effect—on account of the very high pressure under which the gas is in the bottle—is unpleasant, perhaps dangerous. A severe shock is felt in all the abdominal organs.

Von Ziemssen ("Die künstliche Gasaufblähung des Dickdarms zu diagnostischen und therapeutischen Zwecken," *Deutsches Archiv für klin. Med.*, Bd. xxx., p. 225), recommends for certain cases inflation of the large intestine by carbonic acid. His method is to develop the gas within the intestine, by introducing through a rectal tube, first, bicarbonate of soda, then water, and finally, tartaric acid. He used this method both for purposes of diagnosis and to cause sudden dilatation of the bowel, in order to reduce abnormal positions, strangulations, intussusceptions, etc.

I have never employed Ziemssen's method in the affection we are speaking of, but it may suggest itself in cases where a certain apparatus which I shall describe is not at hand.

The apparatus I employ for the purpose of inflation is an invention of Dr. Robert Rohland, of this city, constructed originally to apply the carbonic acid gas douche to the male sexual organs in the treatment of impotency, and to the vagina in the treatment of certain uterine diseases.

This apparatus, or rather the modification of Dr. Rohland's apparatus, consists of a bottle holding a pint or more, with wide neck, and rubber stopper perforated so as to admit a tube, with the nozzle of a rectal syringe attached to it. To prevent the escape of the gas from the rectum is desirable; a rubber valve to close the anus is attached a short distance below the point of the nozzle. In some cases the valve can be dispensed with, in others a rectal tube may have to take the place of the nozzle.



A solution of six drachms of bicarbonate of soda in about eight ounces of water is introduced into the bottle, and four drachms of *crystallized* tartaric acid (if pulverized acid is used the development of the gas goes on too rapidly) are added. The bottle is then quickly closed, and the carbonic acid rises through the tube, the nozzle of which has been placed in position before the tartaric acid is put into the bottle.

The apparatus of Bergeon for gaseous enemata will also serve admirably well, but it will not be worth while to procure one for such cases as these.

In mentioning Bergeon's apparatus, I may be allowed to call attention to an observation made by me in 1883, before Bergeon's method was published, and which I gave in the above-quoted paper.

My patient, whom I successfully treated for dysentery by means of carbonic acid inflations of the rectum, was afflicted with pulmonary phthisis. While she recovered from her dysentery by being treated with carbonic acid gas inflations of the rectum, her diseased lungs improved likewise. I could have anticipated Bergeon if I had drawn conclusions from this coincidence.

208 Second Avenue.

The History of a Quack.—Dr. Edward Storck, chairman of the Erie County Censors, has lately driven "Professor Legrand," alias "Dr." Geismardo, from Buffalo. The "professor" gave free lectures and healed by his "magnetic touch," caused by an electric belt concealed in the palm of his hand. He had three or four dummy patients travelling with him, who came up on his platform and were healed. He has been in the Oregon penitentiary for rape, by infecting a patient with venereal disease in treating her for "pruritus of the scrotum" with his "magnetic probe." He has been driven out of Denver, St. Louis, Kansas City, Chicago, Milwaukee, and Boston. He married a widow in Chicago, and was arrested for misuse of her money. The State Board of Health drove him from Illinois.

REFLEX INFLUENCES IN THE PRODUCTION OF NASO-PHARYNGEAL CATARRH.[1]

By ALBERT H. BUCK, M.D.,

CLINICAL PROFESSOR OF THE DISEASES OF THE EAR, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

In the present paper I propose to call attention briefly to those comparatively remote exciting causes of naso-pharyngeal catarrh which act—so far as we are able to-day to explain the mechanism of their action—through the intervention of the vaso-motor fibres of the sympathetic nerve. Of the direct exciting causes of naso-pharyngeal catarrh we know very little. Certain kinds of dust and smoke, the pollen of certain plants, the decomposing secretions of the parts themselves or of adjacent organs, and, to a certain extent, the direct influence of heat, cold, and moisture upon the parts, comprise very nearly the entire list of the direct causes known to us. Of the indirect causes acting through the vaso-motor nerves, the commonest and best known is chilling of the surface of the body. If we might believe certain English and American authorities, affections of the teeth should rank next to chill in order of frequency. Possibly this may be the fact, but it has not fallen to my lot, in actual practice, to see more than a very few cases of which I could say that some dental disturbance was apparently playing the part of a promoter of the naso-pharyngeal catarrh—or of the aural disturbance, if the case in hand were complicated, as it often is, with an affection of the ear. The fact is, that we do not yet possess such trustworthy data in regard to the relative frequency of these indirect causes that we can venture thus to classify them. I will therefore simply enumerate some of those which I have observed in practice.

Irritation of the gastro-intestinal tract is, in not a few cases, a very strong exciting cause of naso-pharyngeal catarrh and of all the aural disturbances growing out of such a catarrh. While in most of these cases the evidence of such a relationship is not clear and well defined, it now and then happens that the patient is able, from a habit of close observation, to give the sequence of his symptoms in such a manner as to practically demonstrate the existence of a causative relationship between the gastro-intestinal trouble and that of the naso-pharynx and ear. Thus, for example, in one instance which came under my observation, the patient, who was about forty-five years of age, and had for years been more or less of a sufferer from naso-pharyngeal catarrh with tinnitus aurium and slight impairment of the hearing, and who, more recently, had begun to suffer from feeble digestion, observed that whenever he indulged in certain articles of food he would experience abdominal discomfort, and at the same time a marked exacerbation of his naso-pharyngeal catarrh. So long as the offending substances were in the stomach, he experienced only a slight sense of discomfort; but after they had left the stomach—that is, in the course of three or four hours after he had eaten—a slightly painful peristaltic movement of the bowels would set in, and simultaneously the secretion from the vault of the pharynx would become unpleasantly active, and the singing in his ears would become troublesome. This state of things would last for an hour, or at the most two hours, and then the abdominal discomfort and the other symptoms named would gradually disappear; or rather, the naso-pharyngeal catarrh and the tinnitus would return to their habitual state of slight and comparatively insignificant activity. These attacks were invariably accompanied by the escape of large quantities of gas from the stomach by eructation, and sometimes by a few qualms of nausea.

This case, it seems to me, affords unmistakable evidence that an irritation of the small intestine may, in the presence of a pre-existing naso-pharyngeal catarrh, excite that affection to greatly increased activity. There are many individuals in whom we have every reason for believing that the gastro-intestinal tract is habitually in a state of greater or less irritation. These persons are usually men between the ages of forty and sixty, and it is a very common experience to find the faucial mucous membrane in such patients red and swollen. Can we entertain any reasonable doubt, in these cases, that we are dealing with a naso-pharyngeal catarrh of reflex origin, and that the underlying disease which claims our chief attention as therapeutists, is the gastro-intestinal affection?

---

[1] Paper read at New London, Conn., July 17, 1888, before the American Otological Society.

Reflex influences involving the vault of the pharynx and the ear may emanate, I am convinced, from still more remote organs. A lady, about forty years of age, and otherwise in good health, consulted me for the relief of a distressing tinnitus involving both ears. She had experienced the symptoms of a mild naso-pharyngeal catarrh from time to time during a period of many years. The hearing had not been affected and there were times when she was almost entirely free from the tinnitus. Her digestion had always been good. I saw her for short periods at intervals of a few months, and always succeeded in giving her prompt relief by applying a moderately strong silver nitrate solution, with a mop of absorbent cotton, to the vault of the pharynx, on alternate days. There came a time, however, when these applications failed to give the desired relief. The tinnitus became almost unbearable. I then learned from the patient that she had been a sufferer for many years from pain in the pelvic region and back, and that at this particular time she was suffering to a more marked degree than usual. I urged her to consult a specialist in reference to the suspected uterine disease, and she finally but very reluctantly consented to do so. In this way it was ascertained that the fundamental trouble was a retroversion of the uterus, associated with a chronic subacute parametritis, which from time to time, under the provocation of too much running up and down stairs, etc., became acute. Under proper treatment the parametritis was subdued, the uterus was restored to its proper position and kept there by means of a suitable pessary, and, finally, without any further local treatment of the vault of the pharynx, the tinnitus gradually disappeared altogether. From that time to the present (a period of about one year) the naso-pharyngeal catarrh and the distressing subjective noises have been so slight as to require no further use of the silver solution.

The case which I have just narrated in outline is the only one of the kind that I remember to have seen. However, it has impressed me with the belief that I shall encounter similar cases not so very infrequently hereafter, and that their apparent rarity in the past has probably been due to the fact that I had not given much thought to the probability of such a connection existing between the two diseases, and consequently did not make any effort to ascertain whether any inflammatory action was going on within the pelvic cavity, or not.

The question may suggest itself to some, Are not the reflex influences already referred to competent to act as the direct causes of a naso-pharyngeal catarrh? As will have been remarked, I have spoken of them only as indirect causes, that is, as factors which are competent to aggravate and heighten a pre-existing but perhaps more or less latent catarrhal disease. I see no fundamental reason, however, why these reflex influences may not also, in certain cases, play the part of direct exciting causes; but I think it would be almost impossible to demonstrate the correctness of this belief, and therefore I prefer to adopt the view which assigns to them a less independent rôle.

Saccharin is said by Dr. James Little to prevent ammoniacal decomposition of urine, and hence is valuable in chronic cystitis. It is given internally in doses of about six grains daily.

Clinical Department.

CASE OF DOUBLE PRIMARY EMPYEMA, WITH RECOVERY.

By HERMAN C. GARDINIER, M.D.,

TROY, N. Y.

I was called by Dr. B—— to aspirate the chest of G. A——, aged fifteen, April 8th, at 9 P.M. I found the patient in extreme orthopnœa, with his hands on his knees, panting loudly; respiration, 44; pulse, 130. The lips were cyanosed; skin pale and livid; great beads of perspiration were on the forehead; the boy was very anxious; had a distressed look about the face, and spoke in broken sentences.

There was no chest expansion, but some elevation, the scapulæ moving slightly upward and outward. Both sides of the chest were enlarged, the intercostal spaces of both sides being effaced.

The apex of the heart was pushed downward and inward, beating beneath the xiphoid cartilage. No vocal fremitus was heard below spines of scapulæ. There was marked flatness on the right side from the spine of the scapula downward; the flatness in front beginning at the third rib. The liver was pushed a little downward, but was not tender nor enlarged. Voice sounds and respiratory murmur were absent posteriorly from the spine of scapula downward; no egophony. In the interscapular, axillary, and infraclavicular regions there was marked bronchial breathing. On the left side there was flatness from the angle of the scapula downward; fremitus, vocal resonance, and vesicular murmur were absent. Distinct bronchial breathing was heard in the high axillary and interscapular regions. Heart-sounds normal; pulse of good strength, not intermittent. He had several days previously had slight pain in the right axillary region, and a few days later had pain beneath the left nipple, and considerable colicky pains in abdomen, with vomiting. He was perfectly well until the appearance of pain in right chest. A few days after the blizzard, in March, he got his feet wet. There was no phthisis in the family. Urine: Specific gravity, 1.018; reaction acid; no albumin or casts.

I aspirated in the seventh intercostal space on the right side, and withdrew three pints of pus, with great relief to the breathing, the patient passing a very comfortable night. The following day I was called at 10.30 P.M., and found the patient in great distress; pulse, 130; respiration, 40; temperature, 102° F. I then aspirated in the seventh intercostal space, on the left side, and withdrew two pints of pus, considerably thicker than that taken from the right side. The boy was much relieved; the lung immediately expanded; the color improved, and he passed a good night. The next evening, at 5 P.M., the patient was again distressed in breathing and cyanotic; respiration, 40. I found that fluid had reaccumulated on the right side, and I again aspirated and drew off two pints of pus; the lung expanded well, and the patient passed a comfortable night. On the next evening, at the same hour, I aspirated the left side, but the pus was too thick to run through the largest needle. I then tapped the right side, and drew off one pint of pus. On April 12th I thought proper to introduce a drainage-tube in the left side of the chest. Dr. Leroy McClean was called in consultation. We gave the patient a few whiffs of chloroform; the side had been previously rendered aseptic, and Dr. McClean introduced a double drainage-tube through the eighth intercostal space; about one pint of pus came out of the opening. On April 21st a drainage-tube was introduced on the right side by Dr. McClean, in the seventh intercostal space, in the axillary line; about half a pint of thick pus came out of the opening. At 5 P.M.: Temperature, 101½ F.; pulse, 124; respiration, 40; both sides were washed out with a solution of chlorinated soda.

The patient passed a comfortable night, and ate a good breakfast the next morning. The lips were of good color, and he appeared cheerful. Good vesicular murmur was heard in front as far as fifth intercostal space on both sides.

April 23d.—Passed a good night; has an irritative cough; heart-sounds normal; apex beneath sixth rib to left of sternum.

On April 28th, after a good night, the patient was awakened at 5 A.M., when a large fibrinous plug came out of the opening on the right side, affording him great relief. Good vesicular murmur could be heard in front on the right side down to the sixth rib, and posteriorly to the angle of the scapula. On the left side the vesicular murmur could be heard as far as the fifth rib anteriorly, and two inches below the angle of the scapula posteriorly. Both sides were washed out with sol. bichloride 1 to 10,000.

May 5th.—Has a splendid appetite; no cough; is gaining flesh; passes comfortable nights; can lie almost horizontally; temperature normal; one ounce of fibrinous flakes from right side, and three ounces of pus without odor was discharged from the left side. Respiration, 36; pulse, 116; examination of urine gave negative results.

May 11th.—No discharge from the left side; about one and a half ounce from the right side. The patient is improving in flesh and strength, and is able to walk around the room. The heart's apex is in the right situation. There is no curvature of the spine, but considerable retraction in the left inframammary and lower axillary regions, with considerable prominence of the lower portion of the sternum. The right inframammary region is slightly retracted. Good vesicular murmur can be heard on the left side three inches below the angle of the scapula; some crepitation at the base of both lungs.

June 1st.—Respiration, 22; pulse, 100; temperature has been normal for ten days. There has been no discharge from left side for fourteen days, and the drainage-tube was removed and the opening allowed to close, but two drachms of gelatinous-like substance came from the right side.

June 24th.—There has been no discharge for five days from the right side; the temperature has been normal for thirty days; pulse ranges from 80 to 100; good vesicular murmur to the very base of the left lung, and to the sixth rib anteriorly. The patient has gained much in flesh, has a good appetite, sits up most of the time, but is very pale. The drainage-tube was removed from the right side and the opening allowed to close. There is very little chest expansion, the scapulæ move but slightly. The left side measures, from spinous process of the mid-dorsal vertebra to the mid-sternal region, just above nipple, 14 inches; on the right side, $14\frac{3}{4}$ inches. The circumference at the same level, during quiet breathing, is $28\frac{1}{2}$ inches; in forced inspiration, $29\frac{1}{4}$ inches.

June 27th.—Patient was taken to the mountains; respiration, 20; pulse, 80; good vesicular murmur to base of both lungs.

THE PERFECT VAGINAL TAMPON.

By ROBERT T. MORRIS, M.D.,

NEW YORK.

If there *is* anything new in my method of constructing and using this tampon I am sorry, as the satisfaction derived from the results of its employment is so great that I would gladly hear that the thing has been used for many years by many men.

Adopting Wylie's suggestions as to the form of a cylindrical tampon, to be made with absorbent cotton, and the idea of some one else as to the value of wool,[1] I combined the two in such a way as to please patients.

It is not easy to give the exact proportions of cotton and wool to be used; but, like a woman's receipt for cake, we take "about so much of each ingredient." The wool is wound, with several half-hitches of thread, into a loose elastic cylinder two or three inches in length, and about one inch in diameter. This cylinder is then covered with a layer of absorbent cotton one-quarter of an inch thick, except at one end, where the wool is allowed to protrude a little. The cotton is bound on with three or four more half-hitches of thread.

The tampon, now complete mechanically, is dipped into Wylie's solution (alum, ʒ ij; boroglyceride, ℥ j; glycerine ℥ iij.), and it is then complete chemically. It is inserted with the aid of a Sims speculum and long forceps. Hamilton's bullet forceps are the best ones for the purpose.

The philosophy of the apparatus is as follows: The elastic wool centre prevents the cotton from contracting into a hard mass, and it acts as a drainage-tube because, being non-absorbent, it allows fluids to percolate freely through it. The end of wool which protrudes from the tampon nestles just within the sphincter vaginæ, and, being springy and spready, it prevents the tampon from slipping out.

The absorbent cotton-covering holds the medicated solution in contact with congested tissues, and allows of transmission of discharges into the wool centre.

The glycerine, because of its affinity for water, causes a rapid exosmosis of serum from congested tissues, and in such quantities that a patient will frequently have to wear napkins to catch it. The alum acts in its well-known way as an astringent; and the boroglyceride as an antiseptic prevents fermentable fluids within the vagina from decomposing. This tampon, above described, may be left in the vagina for several days at a time, and it will remain neat and sweet, and will not irritate the membranes with which it comes in contact.

In a case of ordinary catarrh of the cervix uteri, with obstructive dysmenorrhœa and congestion of the uterus, I would use the tampon in the following way: It would be introduced once every four days until there was a marked decrease in the evidences of inflammation. I should then give the patient laughing-gas or chloroform, dilate the cervix uteri widely, swab out the uterine canal with absorbent cotton held in Hamilton's bullet forceps, wash out the uterine canal with 1 to 30 carbolic-acid solution injected through an Otis urethral cocaine injector, and should finish the operation by inserting a glass or hard-rubber intrauterine drainage-tube dipped in Wylie's solution. The tampon should then be inserted into the vagina, and left in place for two days. I should then remove the tampon and the tube, and should reinsert the tampon once in every four days thereafter, until the patient was sufficiently happy.

In a case of retroversion of the uterus, in which the organ could be easily replaced, the patient would be put in the knee-chest position. Air being then allowed to enter the vagina the tampon should be inserted in such a way as to extend into the space behind the uterus, the free-wool end resting just within the sphincter vaginæ.

In a case of chronic pelvic cellulitis, in which the tampon would be used simply as a carrier of the medicated solution, it would be advisable to make a fresh application every day or every other day.

It is not necessary for me to go into further details. A little practice is required for making this perfect tampon; but when one has become somewhat expert at it the apparatus will give greater satisfaction than any other one thing that I know of as a medical or surgical appliance. The question as to the exact size and shape of the tampon for any given case is to be decided, of course, at the bedside. One of my patients, who has a cystocele and a retroverted prolapsed uterus, is wearing a tampon nearly five inches long, flattened, and about two and one-half inches broad. Another one, a delicate little virgin, with catarrh of the cervix uteri, is wearing a tampon about an inch and a half long, round, and three-quarters of an inch in diameter.

---

[1] Surgeon's wool. To be obtained at all wholesale drug houses at about one dollar and fifty cents per pound.

Some of the tampons that are made after my description will not have a projecting tuft of wool at the lower end, and the makers will wonder why the apparatus does not stay in the vagina better. A majority of first specimens will be wound so tightly that the uterus will be irritated, or so loosely that the uterus is not comfortably supported.

APHASIA OCCURRING DURING THE SECONDARY STAGE OF SYPHILIS.

By JOHN S. WILSON, M.D.,

HOUSE-SURGEON, CHARITY HOSPITAL.

PROBABLY no organ or tissue in the human body enjoys an immunity from attacks of syphilis. The firm bony structures suffer as well as the more delicate glandular and nervous tissues. The following history, which is rather out of the ordinary run of cases, is that of a patient in one of Dr. Burchard's wards in Charity Hospital.

Annie C——, thirty-eight years of age, came under observation February 7, 1888, with her first venereal trouble. She firmly denied all subjective and objective symptoms of a previous syphilitic history. She presented herself with a diffuse papulo-squamous eruption of four weeks' duration, and had adenopathies and osteocopic pains, but no alopecia or sore throat. She was put upon hydrarg. iod. virid., gr. $\frac{1}{5}$, t.i.d. She then pursued an uneventful course until May 1st, when she began to complain of a severe localized headache, which was worse at night. This resisted antipyrine by mouth and hypodermatic injection. At this time, her gums becoming tender, the inunction of hydrarg. oleat. was substituted for the protoiodide, and in addition she was given potass. iod. in increasing doses. Suddenly, on the afternoon of May 12th, she was attacked with atoxic aphasia. The only word she spoke was "Yes." She answered "Yes" to every question, but realized her mistake. On the following day she said "All right," and from that time her vocabulary has gradually increased, until three months after the attack of aphasia she has full control of her speech. During the attack she understood remarks addressed to her, but answered with "Yes" or "All right."

At this time her pulse, respiration, and temperature were normal; there were no convulsions or mental disturbance. Diminished sensation and reflexes were observed in the right upper extremity, with paresis of the same part, and also of the right side of the face.

Pupils equally dilated; respond to light and accommodation. Possibly it may be said her aphasia was accidental and intercurrent, and wholly unconnected with her syphilis. In answer to this we find an absence of the usual causes of aphasia, such as alcoholic history, atheroma, cardiac and pulmonary history, traumatism, mental tension, etc.

There are two points of interest connected with this case. One is the early appearance, in the course of syphilis, of such a marked cerebral disturbance as aphasia. Such decided nervous symptoms are, in the vast majority of cases, seen later in the course of the disease, and are usually due to the presence of gummata. The other interesting feature of the case is the question of the diagnosis of the cause of the aphasia. This is, of course, more or less a matter of speculation. We know that syphilitic disturbances of the nervous system may be due to affections (1) of the bony encasement, (2) of the meninges, (3) of the parenchyma, and (4) to that little known derangement about which we confess our ignorance when we call it *sine materia*.

The aphasia, in the case before us, can hardly be due to a gumma of the skull, for these very rarely appear before the second or third year, and usually not before the twentieth year, or even later. Dry caries, necrosis, nodes, etc., are lesions of the tertiary stage, while our patient was in a blooming period of the secondary stage. Again, the lesions of the meninges are an accumulation of small cheesy or gelatinous gummatous deposits, situated upon a more or less deeply injected membrane. These deposits rarely accompany the secondary stage. Our patient recovered too rapidly to have been the subject of a diffuse encephalitis; nor did she give evidence of so grave a lesion, except a persistent and localized headache. Dr. Otis believes that nervous symptoms occurring during the secondary stage are due to pressure from the development of "an accidental papule, or its equivalent, within the skull, or in the track of a nerve."

Others lean to the idea that the early appearance of such symptoms is due to some derangement of the circulation within the cranium and leaves no post-mortem changes (*sine materia*), or are due to the poisoning of the nerve-cells by the specific virus of syphilis.

TIC DOULOUREUX OF SEVENTEEN YEARS' DURATION TREATED BY NEURECTOMY.

By W. A. HOWE, M.D.,

PHELPS, N. Y.

ONE of the most interesting cases that has ever commanded the attention of the medical profession in this vicinity is that of Mrs. T——, who during the past seventeen years has been almost a constant sufferer with most excruciating neuralgic pains. These pains would recur at intervals varying from a few minutes to several hours, and were always experienced in those regions of the face which are supplied by the supraorbital, infraorbital, and mental nerves. Their persistency during all this time has occasionally been interrupted by some energetic plan of treatment; but such relief afforded by drugs proved but of short duration, and she soon lapsed into as fearful a condition as before. Prompted by a knowledge of this repeated failure of drugs, and believing surgical measures would relieve her, I determined, if her consent could be gained, to resort to such a procedure. Being somewhat advanced in years, and fearing that serious consequences might possibly result, she was at first rather reluctant to give her consent to any surgical treatment. After explaining its perfect freedom of danger, however, and assuring her that there were chances of its effecting permanent relief, she finally yielded to my request and submitted herself to the trial. In accordance with her desire only one nerve was excised at a time. The treatment was begun on May 29th, at which time the supraorbital nerve was operated upon. Its point of exit from the skull having been ascertained by means of the notch through which it passed, fifteen minims of a four per cent. solution of cocaine were injected directly over the nerve. One clean incision was then made, as near as possible along its course, for somewhat over an inch. My dissection was next carried down to the nerve, which was at once exposed and divided at its distal end. Using this cut end as a guide, I proceeded to follow the nerve as far as possible in the direction of the infraorbital notch, upon reaching which another division was made, thus enabling me to remove in the neighborhood of an inch of the nerve itself. No pathological changes presented themselves in or about this nerve. Strict antiseptic principles were observed throughout, and the wound necessitated by the operation completely healed by the thirteenth day. From that time on, the patient enjoyed entire freedom of all pain in the regions supplied by that nerve.

Encouraged by the result so obtained I felt still more justified than before in prosecuting the same line of treatment. Ten days later I therefore performed a similar operation, at which time a portion of the mental branch of the inferior maxillary nerve was excised. As in the former case, cocaine was injected and a single incision employed. Instead of finding the nerve normal in appearance, as before, there was here seen a marked neuritis. This inflammation involved not only the connective-tissue sheath but the nerve-elements themselves, and extended along the nerve as far as I was able to examine with the length of the incision used. Besides these pathological changes in the nerve itself, there was also found a small abscess in contact with, though not adherent to, the nerve. The neuritis directly under this abscess was more intense in character than that present in adjacent parts of the nerve, which fact explains the extreme localized tenderness which the patient had experienced in that particular spot. No further changes were detected in this region. The wound occasioned by this operation also healed by first intention, and the patient suffered no further paroxysms along the course of the resected nerve. Urged by Mrs. T—— to rid her of the only remaining pain, I completed the treatment, three days later, by excising a portion of the infraorbital branch of the superior maxillary nerve. Marked pathological changes were here seen, corresponding in character and degree with those found in and about the mental nerve. The abscess in this case might have been a trifle larger, but except that no pathological differences manifested themselves, equally favorable results were here obtained, and my patient during the next four weeks gave not the slighest indication pointing to a recurrence of the pain. During this time she regained her sleep at night, and grew stronger and better in every particular. While everything thus seemed indicative of a most favorable issue, she was suddenly seized with a severe attack of choleraic diarrhœa, from which she died in a few days. As I fully appreciate the probability of a regeneration of the nerves so destroyed, I shall not attempt to say how long such relief would have continued; yet considering the torture which she had suffered, the freedom from danger of the operations, and the perfect relief afforded her, even though it might have lasted but a few months, I can but believe in the expediency of such a plan of treatment for facial neuralgia of such an obstinate character. It seems especially applicable where there are existing reasons sufficient to warrant one in believing a local condition is responsible for the recurring paroxysms.

TWO PLACENTAS—ONE CHILD.

Dr. Charles A. Church, of Bloomingdale, N. Y., reports the following case : "On June 9th I was summoned to attend Mrs. S. W——, aged thirty-nine, in her eighth confinement. The case progressed naturally, the position and presentation being normal, until the third stage of labor. After waiting a few minutes for a contraction I made gentle pressure at the fundus, and a placenta of natural size and shape was expelled, yet there seemed to be something to prevent extracting the remaining secundines. About this time the uterus relaxed and a severe hemorrhage set in, necessitating immediate action. I introduced my hand to near the fundus and extracted another placenta similar to the first one, excepting in size, the second being only two and one-half inches in diameter. It had a cord of proportionate size, composed of a vein and two arteries, the latter being twisted around the former the same as in the larger cord. The smaller cord was ten inches in length and joined the cord from the larger placenta about half way to the child. This case is of anatomical interest on account of its rarity, and of clinical interest from the fact that without care the second placenta might have been overlooked, and either hemorrhage or septicæmia have been the result."

ANTIPYRINE IN CEPHALALGIA.

Dr. F. Tuckerman, of Newport, R. I., writes: "If antipyrine is not a specific in certain forms of cephalalgia it certainly comes nearer to it than any preparation with which I have experimented. I have been subject to periodical headache of a nervous character and very severe type for nearly fifteen years, and during that time have employed most of the suggested remedies for that disorder, but with little or no beneficial result. Some time ago I tried antipyrine in single doses of ten grains (taking the remedy as near the onset of the attack as possible) with decided success. Almost immediately the paroxysm is lessened, and within an hour or two there is complete relief. Rarely I have increased the dose to fifteen grains, but in no instance has it been necessary to repeat it during the same attack. In addition to the immediate relief afforded by the use of antipyrine the individual attacks are rendered far less frequent, are shorter in duration, and are less intense in character than formerly. Upon others, for whom I have prescribed antipyrine in this disorder, the effects have been much the same, only less marked than in my own case. I consider antipyrine of special value in certain forms of cephalalgia, but not in all forms, as some observers assert. In occipital headache it almost invariably gives temporary relief and at the same time tends to prevent a recurrence of the attacks. In frontal headache and in headache depending upon a derangement of the digestive apparatus I have found it of comparatively little use."

A WOOLLY-HEADED CHILD.

Dr. B. J. Wetherby, of Arlington, Kan., writes; "I desire to place on record an account of what I consider a queer freak of nature, with a view of bringing out similar cases, if there are any such. I was called to see a child that was having convulsions and found the convulsions due, probably, to a very high temperature, the result of an acute attack of indigestion. On first seeing the child, my attention was called to its hair, or, more properly speaking, to its wool, for in the place of hair its head was covered with a thick growth of white wool, looking exactly like the wool on a young white lamb. As the child was very sick, and its parents excited and anxious, I did not ask any questions. At my visit next day, however, the child was much better, and I found on inquiry that it was four years old, very bright and intelligent, and in every other respect well developed for a child of that age. The growth was congenital, but of course much shorter at birth. She has several brothers and sisters, who have fine heads of hair. The father and mother both have fine heads of dark hair. There is no African blood in the family. On examining the wool I found it was real wool and not hair. Her mother tried to comb it while I was present, with the result of ploughing a sort of furrow across the head. Her mother's theory is that it is a 'birth-mark;' during her pregnancy she had a pet lamb that she thought a great deal of—feeding and caring for it and keeping its fleece clean. Now, can this be what she believes it is—a birth-mark? Has anyone ever seen a similar case?"

UNSUCCESSFUL VACCINATION AND IMMUNITY AGAINST SMALL-POX.

Dr. Walter Reed, Assistant Surgeon U. S. Army, of Mt. Vernon Barracks, Ala., in reference to this question, reports the following case in the affirmative : "During the summer of 1871, while an interne in the Kings County Hospital, Flatbush, L. I., I vividly recall the mental trepidation with which one of my fellow-internes looked forward to his month's service in the small-pox hospital, then a branch of the Kings County Hospital. This anxiety was due to the fact that he had again and again been unsuccessfully vaccinated, during childhood and adolescence, with both humanized and bovine virus. I remember that it was a subject of discussion among us whether, not being susceptible to the vaccine virus, he could acquire small-pox, and although the drift of opinion was against the probability of his taking the disease, this did not quiet the solicitude of the unsuccessful candidate for vaccination. Hence, to make matters doubly sure, during the month immediately preceding his service in the small-pox hospital he was several times very carefully vaccinated, but with negative results. All precautions having thus been taken, when the day arrived for Dr. —— to assume control of the small-pox wards he bravely 'faced the music,' as doctors always do, and was, therefore, for the period of one month daily, and, I might say, hourly, by the bedside of the most virulent cases of confluent and hemorrhagic small-pox *without acquiring the disease.* If any doubter believes that this individual's insusceptibility to vaccinia did not give him immunity against variola, I should be pleased to hear the explanation."

ACRANIA.

Dr. J. F. Lockwood, of Batavia, Ill., reports the following case: "Mrs. S——, a native of Sweden, primipara, gave birth to an acephalic female child. It was still-born and there was no response to the artifical efforts, yet quickening was felt to the last by the mother, and I myself, while manipulating, felt muscular effort on the part of the child. It seemed to be at full term, *i.e.*, otherwise fully developed. The peculiar features of the case were as follows: First, as to the conduct of delivery. I could not feel the parts of the child with my finger in the vagina, although the os was well dilated and the bag of waters was prominent and easily ruptured. The amount of amniotic fluid was very great. After the rupture of the membrane, the breech presented and was delivered at the end of four or five hours. The cord was coiled once around the right leg just above the knee. I anticipated trouble in delivering the head, but found no opposition to its passage, for this stage was soon completed and the explanation came with it. There was no skull and no scalp. The hemispheres were small and unprotected, and the outer integumentary covering to the spine was also lacking. I suppose the removal of the pressure from the exposed and partly developed cerebrum was the cause of death."

The Pupil as a Guide in the Administration of Chloroform.—As a result of experiments upon animals and of observations made upon man, Dr. H. I. Neilson formulates the following conclusions: 1. The first effect of chloroform narcosis on the pupils consists in a dilatation which varies in intensity and duration in different individuals. As the anæsthesia becomes more profound the pupils then begin to contract, and finally become very small and immovable. If now the chloroform is pushed still further, a sudden dilatation occurs, which is the result of asphyxia, from which the patient seldom recovers; 2. As long as the pupil is observed to dilate in response to sensory stimuli, such as pinching the skin, the anæsthesia is not yet sufficient to allow the commencement of the operation; 3. As soon as the pupil becomes strongly contracted and immovable the administration of the anæsthetic must be suspended until a commencing dilatation is observed, and the patient must be held at just this point as long as the operation continues; 4. Vomiting causes a dilatation similar to that occurring as the patient emerges from the narcotic condition, but it is usually more sudden in the former case. In experiments upon dogs it was found that the contraction of the pupils did not begin until the blood-pressure was somewhat reduced, and that the dilatation proceeded *pari passu* with the increase in the blood-pressure. The author regards the appearance of the pupil as a very reliable guide for the administration of the chloroform, as by it he is enabled to judge accurately concerning the condition of the patient.—*La Riforma Medica*, June 23, 1888.

The Vapor of Tar is said by Dr. Mills, of Glasgow, to be injurious to many persons, causing in them nausea and giddiness.

Progress of Medical Science.

Healing of Nerves by First Intention.—Dr Cavazzani has made a number of experiments upon dogs to determine the period of the restoration of conductivity in divided nerves. He divided the median or sciatic nerve with scissors and immediately sutured the severed ends with catgut. In one case the power of motion in the muscles supplied by the wounded nerve returned in five days, and in another case in eight days. From this he was led to conclude that divided peripheral nerve-fibres may unite, like other tissues, by first intention.

Abdomino-vaginal Complete Hysterectomy for Uterine Fibroids.—Prior to operation on a case of fibroids of the uterus recently, Mr. Reeves stated that he intended to adopt a new plan which had occurred to him, provided that the relations of the growth permitted it. If, on opening the abdomen, the tumor proved to be an ordinary form of fibroid involving the fundus and body, and did not extend too far laterally into the broad ligaments, he intended to tie these on either side in two interlocked ligatures, including the upper two-thirds of these structures, and, after applying pressure-forceps to their uterine side, to divide between. Then the peritoneal folds attaching the growth to the bladder and rectum would be divided well up on the tumor, so as to form flaps in the pelvic floor when the growth was removed. The ureters, bladder, and rectum would then be cleared from the cervix until the vaginal mucous membrane was nearly reached, when the vaginal part of the operation would begin. This consists in separating the mucous membrane, as in vaginal hysterectomy. The uterine arteries would be compressed with forceps, to be left on or tied according to circumstances, and the uterus removed entire. The pelvis would be cleansed, the serous flaps placed in apposition, or stitched together if thought desirable, and a drainage-tube inserted *per vaginam.* The subsequent treatment would be as for vaginal hysterectomy. Mr. Reeves explained that his object in combining these plans was to do away with the uterine stump and its disadvantages, such as secondary hemorrhage, septicæmia, dragging on the bladder and rectum, and occasionally the risk of its slipping into the abdomen and causing peritonitis. The combined operation should occupy less time than supravaginal hysterectomy with external treatment of the stump, as much time is taken up with trimming this and suturing the peritoneum over it. Seeing that the best results in the supravaginal operation have been obtained by extra-peritoneal treatment of the stump, and that the mortality is still a high one, any practical plan which will reduce the causes of death should be acceptable. The chief of these are nowadays hemorrhage, septicæmia, and peritonitis, and it is believed that the proposed plan will banish all but a possible traumatic peritonitis; and as in vaginal hysterectomy for cancer this has been practically abolished, there is no reason —except, perhaps, the greater size of the growth removed —why the same favorable result should not follow the proposed operation. Complete removal of the fibroid uterus by Freund's method has been done, but the results of his mode of operating have been far from encouraging. The combined plan suggested allows of free drainage and syringing of the pelvic cavity, and offers every element of operative success, while doing away with many drawbacks. —*The British Medical Journal.*

Pathology of the Ganglion of the Trunk of the Pneumogastric Nerve.—Dr. Alexander Levin, chief of Professor Manasseïn's clinic in St. Petersburg, has published as his graduation thesis an interesting series of observations on the pathological changes in the ganglion of the trunk of the pneumogastric nerve in different diseased conditions. He examined this ganglion in one hundred and two bodies where during life there had been disease of some of the organs receiving their nervous supply from the pneumogastric, including cases of heart disease, pulmonary phthisis, and croupous pneumonia, or where the patient had suffered from some general disease, such as typhoid, scurvy, diphtheria, cholera nostras, hydrophobia, and others. He finds that in typhoid the ganglion is frequently affected by an inflammatory process, there being marked hyperæmia, and sometimes extravasation of blood or granular changes in the nerve-cells, which lead to their atrophy or breaking down, and to hyperplasia of the connective tissue of the nerve. These morbid changes have as their result, as Dr. Levin believes, typhoid laryngitis and paralysis of the pharynx, cardiac irregularities unconnected with high temperature, the so-called "sudden death of typhoid," spasmodic dysphagia and vomiting, and finally, dilatation of the stomach, observed by many authorities in cases of typhoid. In cardiac disease the pneumogastric ganglion is found to be affected by chronic venous stasis, extravasation of blood, thickening of the external tunic of the small vessels and of the walls of the nerve-cells, with degenerative changes in these last. This condition of the ganglion may perhaps be connected with special forms of irregularity observed in cardiac cases, in chronic pneumonia, and often existing in aortic aneurism, and also with paralysis of the pharynx and vomiting observed in some cases of heart disease. In pulmonary phthisis the ganglion of the pneumogastric is found to have undergone degenerative changes of the nerve-cells, which are atrophied, shrunken, or eaten away, the stroma being at the same time hyperplasic.—*The Lancet*, July 14, 1888.

INTESTINAL OBSTRUCTION FROM WORMS.—Dr. Stepp has recently reported the case of a boy, four years of age, who died with symptoms of acute obstruction an hour and a half after medical aid was first summoned. Post-mortem examination showed that the intestine was completely obstructed by a twisted mass of some forty or fifty round worms, lodged just above the ileo-cæcal valve. The ileum contained some thirty five more higher up, and there were a few in the stomach and œsophagus. The boy's mother gave him some "worm medicine" two days before he died, and a meal of smoked bacon and sauerkraut on the following evening. Dr. Stepp thinks that the worms, weakened by the medicine, were dislodged in numbers by the violent peristalsis set up by the injudicious meal of the following evening, and so rolled down in a tangled mass too large to pass the ileo-cæcal valve.—*British Medical Journal*, July 14, 1888.

GOUT IN A YOUTH OF FIFTEEN YEARS.—At a meeting of the Hospitals Medical Society of Paris, held June 22, 1888, M. Gaucher reported the case of a lad, aged fifteen years, without gouty or rheumatic antecedents, who had been complaining for two weeks of pain, with a shining redness and swelling in the metatarso-phalangeal articulation of the great toe. The trouble had appeared suddenly during the night. The speaker believed the case to be one of true gout.

URETHRAL INJECTIONS OF COCAINE FOR THE RELIEF OF NEURALGIC PAINS IN VARIOUS PARTS OF THE BODY.—Mr. E. Hurry Fenwick, writing in *The Lancet* of May 5, 1888, reports the case of a man who complained of constant pain in the face, limbs, and urethra. The latter had existed for five years, and was consequent upon an attack of gonorrhœa. He had had several severe attacks of malaria. The pain in the face and limbs had been so constant and severe that it had forced him to resign a lucrative official position in Servia. Believing that his nervous system was thoroughly demoralized by malaria, and that under these circumstances a urethral granulation might have induced the neuralgia, Mr. Fenwick proceeded to pass an endoscope and examine the urethra. Before doing so he applied a few drops of a twenty per cent. solution of cocaine to the canal. In about a minute the patient exclaimed that the neuralgia in the face and limbs was leaving him, and at the end of a second minute he was entirely free from pain. A granulation patch in the urethra was cauterized, and the patient rapidly recovered. The author was led by this experience to make some experiments upon decapitated frogs, injecting cocaine into the cloaca and then dipping the toes into solutions of sulphuric acid of varying strengths. He concluded, as a result of these experiments, that the application of cocaine to mucous membrane temporarily abolishes the consciousness of weak stimuli, such as would correspond to slight nerve irritations, neuralgias, etc.; but that it has no power whatever over stronger stimuli, such as would correspond to the pain of carcinoma, inflammation, etc. He now proceeded to test this action of cocaine chemically in over one hundred cases of neuralgic pains in various parts of the body. In all cases in which the pain was slight and the cause trivial, a freedom from pain was produced, in from thirty to one hundred and eighty seconds, by the injection of a few drops of a twenty per cent. solution of cocaine into the urethra. He therefore concluded that he had obtained a clinical corroboration of the physiological results of a cocaine application, and he formulated the matter as follows: If pain in any part of the body be due to a *slight* nerve irritation of an unimportant character, a cocaine injection into the urethra will rapidly relieve it. If, on the contrary, the pain is due to severe nerve irritation, a cocaine injection will not relieve it. These facts, Mr. Fenwick thinks, open a large field in the differential diagnosis of the causes of pain, as well as the just estimation of the amount of pain experienced by neurotics and others. He has used these injections largely in the diagnosis of urinary diseases. For instance, in cases of renal pain, if a urethral injection of a twenty per cent. solution of cocaine immediately relieves a pain in the kidneys, he diagnoses a transient or unimportant cause for that pain, such as congestion, uratic urine or grit, colonic pressure, etc. If, however, the renal pain is uninfluenced by such an injection, he gives a more guarded prognosis, and this has been several times verified by the subsequent passage of small stone, or, as in one case, by the development of a renal carcinoma. There are also various vesico-urethral diseases in which cocaine thus used has proved of diagnostic value, as in glans pain, urethral pain, suprapubic pain, etc. Lastly, he states, there is every reason to believe that it will prove of value as a prophylactic agent in warding off, by inhibition, the untoward effects of reflex renal flooding after operations upon the bladder and urethra.

A FOREIGN BODY IN THE EAR FOR EIGHTEEN YEARS.—Dr. Alfred Swann reports, in *The Lancet* of July 7, 1888, the case of a man, aged twenty-seven, who consulted him on account of an irritability of the fauces, particularly on the right side, and deafness on the same side. He said that eighteen years ago, when a child, he was playing with a piece of slate-pencil, and poked it into his ear. He went to a medical man who attempted to remove the body, but did not succeed. Deafness gradually supervened, and unless some conducting medium was used the man could not detect sounds at all. On examining the ear with a speculum, it was found to contain cerumen, but nothing else could be seen. A few syringefuls of warm water and carbonate of soda soon dislodged a long plug of what appeared to be cerumen, but embedded in this was a piece of slate-pencil half an inch long, with its rounded end toward the drum of the ear. Hearing was immediately and perfectly restored, and on examination the tympanum was found to be perfectly whole and healthy. The throat symptoms cleared up in the course of a few days.

MICROKINESIS.—A paper by Dr. Francis Warner, on muscular movements in man and their evolution in the infant, was read at the meeting of the Royal Society on June 12th. In the new-born infant constant movement may be observed in all parts during the waking state; these spontaneous movements, to which Dr. Warner proposes to apply the term "microkinesis," cannot be stopped by external stimuli. This condition becomes gradually modified during the growth and development of the child, and the movements are gradually more and more controlled by external stimuli, while the phenomena termed memory and imitation are evolved. The paper also contained a study of the modes of action of nerve-centres in adult age, and it was suggested that when a co-ordinated movement followed a slight stimulus, temporary unions are produced among the centres, and that the brain-action corresponding to thought is the formation of functional union among cells—the outcome of such functional unions is seen in the movements which express the thought. Dr. Warner described a number of special postures and movements associated with certain states of the brain, and, in fact, affording physical signs by which those states might be recognized.—*British Medical Journal*, June 30, 1888.

ONE-CHILD STERILITY.—Out of 1,081 gynecological cases Dr. Kleinwächter noted ninety where the patients had borne one child at a more or less distant period, and had remained sterile since, although still cohabiting with their husbands. In twenty-one of the cases the single pregnancy had ended before term. He divided the causes of this kind of barrenness into ten groups: 1. Sequelæ of inflammatory processes beginning during the puerperium. 2. Catarrhal endometritis. 3. Sequelæ of inflammatory processes traced to a non-puerperal origin. 4. Displacements of the uterus. 5. New growths in the uterus. 6. Constitutional sources of sterility established after the first pregnancy. 7. Impaired potency of the husband. 8. Excessive involution or atrophy of the uterus. 9. New growths in the ovary. 10. Uncertain or unknown causes. These groups are arranged in order of frequency. Forty-three were traced to uterine and extra-uterine pelvic inflammations; that is, to the first three groups; nineteen to displacements and tumors. Dr. Kleinwächter admitted that the causes grouped above as two and four were not proved in every case to be uncomplicated. He declared that the seven cases making up group seven were well authenticated by the clinical history, the condition in question appearing to act in a positively deleterious manner on the genital apparatus of the woman. Under group six were included cases where anæmia, cachexia, obesity, or emaciation arose after the first pregnancy. Dr. Kleinwächter could come to no conclusions as to treatment, since his cases could not readily be kept under observation after their discharge from hospital. —*London Medical Recorder*, June 30, 1888.

SUSPENSION OF THE UTERUS FOR PROLAPSUS.—Dr. Malanco has recently brought before the Mexican Academy of Medicine an operation which was practised for the first time more than three years ago for the relief of prolapsus uteri, and which, it is claimed, possesses advantages over the use of pessaries and over Alexander's operation of shortening the ligaments. The Mexican operation is denominated "suspension of the uterus," and it has been performed during the course of the last twelve months no less than eight times in the hospital Angel Gonzáles Echeverria in Mexico, the unilateral and bilateral operation being each employed four times. In all the cases the results were satisfactory in a greater or less degree. The operation consists essentially in making a track, whose walls become indurated and indistensible, between the fundus of the vagina and the external surface of the abdomen just above the horizontal ramus of the pubes. At first it was proposed to employ the thermocautery, but this was abandoned on account of the danger of the heat given out by it affecting the peritoneum, and also because it was found that the retraction caused in the subperitoneal cellular tissue was insufficient, though that set up in the dermis is, as is well known, considerable. It was then determined to pass a thread or ligature through the track, and thus temporarily to tie the vagina to the abdominal wall until the tissues had become sufficiently retracted. Catgut was employed for this purpose, but, though admirable for its antiseptic qualities it did not last long enough to accomplish the desired effect. A thread of silver wire has latterly, therefore, been substituted. This is made into a loop, which passes round a bit of metal in a piece of gum-elastic catheter, which acts like the quill in a suture, and is retained in the vagina. The other end is passed out above the pubes, and retained by a piece of lead. Iodoformed ether is injected into both extremities of the canal. Cotton-wool and collodion impregnated with corrosive sublimate are applied to the external wound, and frequent antiseptic irrigations are practised per vaginam, with the object of keeping the internal wound free from septic matter. There is no need to tighten the wire much. It is then well borne, and it can remain until the track around it becomes lined with tissue of a sufficiently resistant character. This, of course, forms a hollow cord connecting the vaginal mucous membrane with the skin of the abdominal wall. In one case by some accident the wire got broken in a fortnight. This was quite time enough to fix the uterus in its proper position. If, however, this kind of thing happens, there is no difficulty in passing a new wire without making any fresh wound. Indeed, the patient herself may be taught, in case of need, to reapply the wire ligature. The advantages of the suspension operation over pessaries are said to be that the vagina is not obliterated or dilated, the neck of the womb is not irritated, and the facilities for cleanliness are perfect.—*The Lancet*, July 14, 1888.

ANOTHER YELLOW-FEVER MICROBE FOUND.—Dr. Paul Gibier, who was deputed by the French Government to investigate the whole question of yellow fever, has just delivered a lecture before the Academy of Sciences in Havana, embodying the results at which he has at present arrived. Before leaving Paris, he felt so convinced of the truth of Dr. Freire's views that he got himself inoculated with some of the cultures which that distinguished Brazilian physician had brought. The first insertion—made with a lancet with great care—was followed by no result whatever. A week later some of the attenuated virus was injected subcutaneously, and this produced such violent effects that Dr. Gibier declares nothing in the world would induce him to submit to a repetition of it. Since his arrival in Cuba, he has made post-mortem examinations of a number of persons who have died of yellow fever, some of the examinations taking place only two hours after death, and one of them within fifteen minutes from the moment life became extinct. The examination of the blood taken from the heart in these cases, as well as the inspection of the urine, the bile, the pericardial fluid, the liver, the spleen, and the mesenteric glands, convinced him that none of these organs contain any microbe. He, however, discovered in the black matter always found in the intestines a bacillus presenting many points of resemblance to the so-called comma bacillus of cholera, being sometimes curved, and occurring in some cultures in a spiral form, possessing also the property of liquefying gelatine. This bacillus, when cultivated in peptonized broth, blackened the sides of the tubes; and when a few drops of the culture were injected into the intestine of guinea-pigs it sometimes proved fatal, the intestinal contents then showing a great resemblance to those found in yellow-fever patients. In dogs, the injection of a few drops into the small intestine rapidly produced violent effects—vomiting, diarrhœa, and, the night following, pyrexia. Cultures of this bacillus had a smell resembling that of the black vomit. A moist heat of 60° C. destroyed the bacillus in a few minutes; desiccation also proved fatal to it in less than twenty-four hours. This last observation led Dr. Gibier to suggest that if this bacillus was really the cause of yellow fever the immunity of inland districts might thus be explained, the comparative dryness of the air destroying the virus. It developed extremely well in sea-water charged with organic matter; living, too, for a long time side by side with the ordinary microbes of putrefaction, so long at least as the medium did not become acid, for even a very slight degree of acidity destroyed the organism in a few hours. In confirmation of observations made at the laboratory, Dr. Gibier mentions that he has several times had an opportunity of demonstrating the same circumstance in the dead-house, the contents of the intestines, when they have become acid some hours after death, ceasing to show the presence of the bacillus. Since writing on this subject previously Dr. Gibier has had opportunities of examining the bodies of foreign sailors who have died in the civil hospital of Havana, and he has been able to demonstrate the presence of the bacillus in those who had suffered from yellow fever, and its absence in those who had died from other diseases. His opinion is that yellow fever is due to the development of the microbe in the intestine, the affection being therefore essentially a local one.

Myxo-fibroma of the Fifth Dorsal Nerve.—This case, recorded by Drs. Bruce and Mott in *Brain*, presented a history of rheumatism for four years before the growth extended into the spinal canal, as shown by the slowly increasing symptoms of pressure on the spinal cord. The diagnosis lay between syphilitic growth, vertebral caries, tuberculous growth, sarcoma, or an uncommon non-malignant tumor. Syphilis was not likely, because of the history and of the failure of antispecific treatment. No cause or sign of vertebral caries existed, and tubercular tumor and sarcoma were improbable, because of the absence of signs elsewhere and of the very slow course of the disease. Myxomata of nerves are not uncommon, nor are those commencing in the meninges rare; but this tumor began in the nerve and spread on to the cord—a decidedly rare course. Such a tumor might have been successfully treated by surgical interference.—*The Lancet.*

Raw Milk and its Impurities.—Dr. George O. Williams, of Greene, Chenango County, N. Y., writes: "While reading the editorial in the issue of June 30th, relating to Dr. Caille's article on sterilized milk, my attention was particularly arrested by its final clause: 'And as between fresh milk and sterilized milk, we think that no one will hesitate to prefer the former.' For the past few years I have pretty thoroughly excluded milk from my list of diets for the sick-room, and I seriously doubt its advisability as food, in its raw state, under any circumstances. It is not extravagant to say that such a thing as 'pure milk' does not appear in market. Nor is it far from the truth that a filthier material is not offered as food. This section has extensive dairy interests. Some of the milk is made into butter on the farm, some collected by cheese factories, a portion is received by large creameries, while a considerable quantity finds its way to the New York City milk-trains. That which is delivered by our local dealers for our own consumption, or that which is received at the milk-depots for transportation to the city, is usually strained once, through a wire strainer attached to the milking pail. It seldom receives more attention than that. The habit of the farmer is to 'milk in' everything that the udder yields, unless the amount of blood from a diseased bag perceptibly tints the milk, or leaves a too highly colored sediment in the bottom. Often it is impossible to detect the presence of the products of garget—mammitis—except by the mechanical separator. In answer to questions which I have asked farmers, as to their custom in disposing of the milk from cows affected with bovine eczema, which during the summer months is always more or less prevalent in every dairy, the uniform answer has been that generally, 'We milk it in.' The same reply was given to the questions as to their habits when cow-pox exists in the herd. In point of fact, anything is milked as long as it will give milk, whether there is eczema, cow-pox, tubercular disease, or anything else in the way of disease present at the time. Now add to these the insoluble materials which unavoidably fall into the pail during the milking process and the soluble matters which during a rainy milking hour trickle down the cow's sides and into the milk, and the whole presents an unwelcome amount of dirt. Let me refer to one establishment. This concern uses the milk from one hundred and forty cows. It separates the cream from the milk while still warm, by the centrifugal separator. After the process is completed, there always remains in the cylinder of the machine a mass of material which is more or less discolored with blood and contains other impurities whose specific gravity permits them to remain there. This material accumulates in quantities varying from one-half to one pound per four hundred of milk. It is not my purpose to describe this refuse other than to say that it presents an appearance that is far from inviting. For an ordinary experiment, let any one examine the quart or more of milk that is deposited at his dwelling, after it has remained quiet for a few hours and the cream has 'risen.' It will be found that every millimetre of its surface shows the presence of extraneous matter. This varies in size from a scarcely perceptible speck to some disagreeably large and suspiciously colored fragments. Now decant, and the bottom of the dish will show the heavier impurities. If the foreign substances in any quart of milk were separated and then mixed with a glass of water, there would be little temptation to drink it. Under the microscope, the débris will be found to contain fragments of digested vegetable fibre, fragments of insects and hair, blood-corpuscles, pus-corpuscles, bovine epithelium, some of which are decidedly ill-looking 'cow-scabs;' add to these the soluble matter that is unseen, but which the taste often betrays, and we have a truthful picture of what 'pure milk' actually is. Now I submit, on the evidence, which may be readily corroborated, whether this stuff is a proper food or not, at least unless its temperature has been previously raised to the thermal death-point of organic matter."

The Small Importance of the Alleged Organisms of Syphilis.—Dr. Smirnoff, of Kazan, has published an account of some investigations he has carried out on the micro-organisms of the secretions of syphilitic sores and papules, and on those contained in indurated syphilides (*The Lancet*). The total number of patients whose cases were examined amounted to one hundred. The preparations were stained according to the methods of Lustgarten, Doutrelepont, Schütz, de Giacomi, and Gram. With regard to the micro-organisms in the secretions of syphilitic chancres and papules, Dr. Smirnoff found that they were by no means constantly present, the prevailing forms being those met with in healthy tissues. In normal secretions of the genital organs bacilli and cocci were present quite as frequently as in syphilitic secretions. After local applications of calomel and iodoform no micro-organisms could be detected in the secretions of syphilitic sores and papules. On examination of indurated syphilitic lesions, he found that not only were micro-organisms not constant, but that they were only rarely present. The soft and moist syphilitic tissues always contained more micro-organisms than those which were dry and hard. In the hard syphilitic products the micro-organisms that were found differed so much from one another that it was impossible to point to any one form as being constant. Finally, Dr. Smirnoff is disposed to deny entirely the existence of syphilitic bacilli in the sense in which they are described by Lustgarten.

The Prevention of Cholera Infantum.—In a paper read before the St. Louis Medical Society (*Weekly Medical Review*, June 23, 1888), Dr. H. F. Hendrix states as his belief, founded upon his individual experience, that cholera infantum will not occur in any case where a plentiful supply of cold water is given at all times and on all occasions, night or day, whenever the little one desires it. And he urges upon all who have the care of children to lay aside any scruple of reserve they have in regard to giving cold water, and to give it freely. Those not able to let their wants be known should have it placed to their lips, and should be allowed to drink until they are satisfied.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, August 18, 1888.

DRINKING HABITS AND LONGEVITY.

THE English alone seem to successfully prosecute the work of collective medical investigation. The most recent report is one prepared by Dr. Isambard Owen, on "The Connection of Disease with Habits of Intemperance." This report embraces an analysis of four thousand two hundred and thirty-four cases, contributed by one hundred and seventy-eight physicians. Each schedule gives the social position or occupation, age at death, and cause of death of the different persons.

They are also classified as regards their drinking habits into, A, total abstainers; B, habitually temperate or moderate systematic drinkers; C, careless drinkers; D, free drinkers; E, decidedly intemperate. When doubt existed as to which class a person belonged, he was placed between, under the head of AB, or BC, or CD, etc. The statistics collected furnished facts, first, as to the drinking habits of the different classes of society; second, as to the longevity of those who drink and those who do not; third, as to the cause of death.

The following is a summary of the conclusions given:

1. That habitual indulgence in alcoholic liquors beyond the most moderate amounts has a distinct tendency to shorten life, the average shortening being roughly proportional to the degree of indulgence.

2. That of men who have passed the age of twenty-five, the strictly temperate, on the average, live at least ten years longer than those who become decidedly intemperate. (We have not in these returns the means of coming to any conclusion as to the relative duration of life of total abstainers and habitually temperate drinkers of alcoholic liquors.)

3. That in the production of cirrhosis and gout, alcoholic excess plays the very marked part which it has long been recognized as doing; and that there is no other disease anything like so distinctly traceable to the effects of alcoholic liquors.

4. That, cirrhosis and gout apart, the effect of alcoholic liquors is rather to predispose the body toward the attacks of disease generally than to induce any special pathological lesion.

5. That in the etiology of chronic renal disease, alcoholic excess, or the gout which it induces, probably plays a special part.

6. That there is no ground for the belief that alcoholic excess leads in any special manner to the development of malignant disease, and some reason to think that it may delay its production.

7. That in the young alcoholic liquors seem rather to check than to induce the formation of tubercle; while in the old there is some reason to believe that the effects are reversed.

8. That the tendency to apoplexy is not in any special manner induced by alcohol.

9. That the tendency to bronchitis, unless, perhaps, in the young, is not affected in any special manner by alcoholic excess.

10. That the mortality from pneumonia, and probably that from typhoid fever also, is not especially affected by alcoholic habits.

11. That prostatic enlargement and the tendency to cystitis are not especially induced by alcoholic excess.

12. That total abstinence and habitual temperance augment considerably the chance of a death from old age or natural decay, without special pathological lesion.

As regards occupation and drinking habits, it appears that the most temperate classes are the professional, clerical, and farming. The persons of most intemperate habits are licensed victuallers, drivers, soldiers, and domestic servants. The independent class rank low, showing that idleness begets intemperance.

The committee's report has an appendix containing the results of a similar inquiry made by Mr. Neison forty years ago, and one made by the Harveian Society in 1879 and 1880. Mr. Neison showed that the mortality-rate among the very intemperate was about five times the general rate. He also found that the intemperate use of spirits was more hurtful than the like use of beer, but that immoderate indulgence in both was more injurious than the exclusive use of either. "Mechanics, working, and laboring men," according to his figures, withstood the effects of intemperance better than "traders, dealers, and merchants," the latter better than "professional men and gentlemen," and all better than women.

The Harveian Society reported that they had reason to think that in London the mortality, among any considerable group of intemperate persons, will differ from that generally prevailing among adults in the following important particulars—namely, a fourfold increase in the deaths from disease of the liver and chylopoietic viscera; a twofold increase in the deaths from disease of the kidney; a decrease of half as much again in those from heart disease; a marked increase in those from pneumonia and pleurisy; a considerable increase and an earlier occurrence of those from disease of the central nervous system; a marked decrease in those from bronchitis, asthma, emphysema, and congestion of lungs; a decrease nearly as great in those from phthisis, and a later occurrence, or at least termination, of the disease; a very large decrease in those from old age, with an increase in those referred to atrophy, debility, etc.; and the addition of a considerable group referred in general terms to alcoholism or chronic alcoholism, or resulting from accidents.

The committee's conclusions under this head roughly correspond with those of the Collective Investigation report as regards diseases of the liver, kidney, and nervous system, and also as regards old age and phthisis, but not as regards diseases of the heart, pneumonia, bronchitis, etc., "atrophy," and debility.

There are, according to Dr. Owen, no statistics aside from his own giving the result of a comparison between the longevity of total abstainers and moderate drinkers.

SEWER-AIR DISEASES.

A GREAT deal of vague assertion has been made with regard to the effects of sewer-gas, or, as it is better called, sewer-air, upon the human system. While some look upon it as always poisonous and often virulent, others consider it usually harmless, though unpleasant. The good health of workmen engaged constantly upon sewers is cited in favor of this latter view.

Dr. Elias H. Bartley attempts, in a recent volume of Wood's "Reference Handbook," to treat the matter systematically, and he has made a very satisfactory contribution to a little understood, though much discussed, subject.

Sewer-air is defined as including the air of house drain-pipes, privy-vaults, cesspools, and other imperfectly ventilated places containing decomposing animal and vegetable matters.

The composition of badly ventilated sewers, according to Professor W. R. Nichols, of Boston, is :

	Maximum.	Minimum.
Oxygen	29 90	20.48
Nitrogen	79.26	78.89
Carbon dioxide	0.50	0.40
Sulphuretted hydrogen	trace	trace

In extreme cases the oxygen has been found as low as 13.79 per cent., the carbon dioxide as high as 3.4, and sulphuretted hydrogen as high as 2.90 per cent. Besides the gases here mentioned sewer-air always contains bacteria and volatile organic matters, sometimes in large amount. The exact nature of these organic matters is not well understood. Some of them seem to belong to the class of bodies known as compound ammonias, or amines. The gases making up sewer-air possess considerable diffusive power, and will pass easily through walls and porous earthenware or brick sewers. In this way these gases frequently find their way into the cellars of houses, especially in the vicinity of a broken sewer or improperly constructed cesspool. Fungi readily grow in such air, and articles of food, such as meat or milk, soon become tainted and decompose when exposed to it. Experience has shown that stagnant sewage gives off more gas and is more dangerous than that which is kept in motion. Sewer-drains which have a steep grade are, therefore, to be preferred to those having a slight grade. Where sewers are frequently flushed with water, and where there is no chance for stagnation, with a reasonably good ventilation, the danger from sewer-air is reduced to a minimum.

There are very strong reasons for believing that the specific poisons, or germs, of a number of the contagious diseases may be transmitted by sewer air. Dysentery, diarrhœa, the periodic fevers, typhoid, cholera, and yellow fever are among the diseases which may be conveyed by sewer-air.

Acute poisoning by sewer-air is comparatively rare, and when it occurs is due generally to the H_2S, or to absence of oxygen.

The symptoms of chronic sewer-air poisoning are of two kinds : the specific and the non-specific. The specific symptoms are those which result from pathogenic micro-organisms of various kinds suspended in the sewer-air and causing the various infectious diseases described.

Among the symptoms, when no specific disease-germs are at work, are malaise, headache, loss of appetite, with dyspeptic symptoms, drowsiness, and slight feverishness. There is a marked tendency to anæmia and general debility. These symptoms are frequently grouped under the name of "malaria." In children, to these phenomena may be added a smooth or glazed, broad, flabby tongue, with a marked tendency to digestive trouble, as vomiting, diarrhœa, dysentery, and attacks of gastric catarrh and catarrhal tonsillitis.

The tendency of sewer-air poisoning is to derange the organs of primary assimilation rather than the lungs; as, for example, gastric catarrh, duodenitis, hepatitis, splenitis, diarrhœa, enteritis, and colitis. Besides these effects, the debilitating influences of the polluted air render the persons so affected an easy prey to an intercurrent malady. Sewer-air is more likely to affect weakly and anæmic persons.

The treatment of chronic sewer-air poisoning is to remove the cause, secure a change of air, and use tonics and symptomatic remedies. The best specific is fresh air.

The methods of detecting sewer-air vary somewhat. The chemical tests depend upon the detection of sulphuretted hydrogen (H_2S) or ammonium sulphydrate. If a piece of filter-paper be dipped in a solution of lead acetate, and be exposed to an atmosphere containing either of these substances, it turns dark-brown, and finally black. A paper dipped in a solution of nitro-prusside of sodium assumes a crimson, and turmeric-paper a brown color with ammonium sulphydrate. White-lead paint is darkened by both the above compounds, while zinc white is not changed in color.

The peculiar odor of H_2S may be easily detected when the proportion reaches one part in 10,000 of air. On closing a room tightly for some hours and then going into it from the open air, a musty or oppressive odor is detected when sewer-air emanations from decomposing animal matters have found their way into it. If any circumstance should lead to the suspicion that sewer-gas is entering a room or house, it would be best to test the drain-pipes by the "smoke test" or the "oil-of-peppermint test."

A suspected joint in a sewer or drain-pipe may be tested by wrapping it with a single layer of white muslin, moistened with a solution of acetate of lead. As the gas escapes through the meshes of the cloth, it will be blackened by the sulphur compounds.

THE CURABLE PERCENTAGE IN GENERAL PRACTICE.

IT is often stated that nine-tenths of patients get well without any medicine, or whether the physician treats them or not. This is a small percentage of cures on the total of all kinds of cases that the physician sees. For example, the percentage of cures in general hospitals receiving acute cases is about ten, while the percentage of reported cures in dispensary practice is, we believe, much greater. Dr. J. R. Uhler, however, in the *Maryland Medical Journal*, who writes with much italicized emphasis, says :

"An examination of one medium-sized practice of medicine *shows* that there are 155 *common medical*, including the *self-limiting diseases*, and *for* 56 *of these* we *can do some-*

thing, either in the way of relief or cure, that is *about* $\frac{1}{3}$. Another practice *gives us* 242, with 68 *curable*, *equal to* $\frac{68}{242}$, rather *nearer* $\frac{1}{4}$ *than* $\frac{1}{3}$, not a very flattering exhibit to be sure; and when the largest books are considered it will probably be $\frac{1}{5}$ or less, say $\frac{5}{24}$, and *at this figure* we will *put it down.*"

THE NEW HYPNOTISM.

Ever since the publication of Bernheim's work on "Suggestion" in medicine, and particularly since the conversion of Professor Forel, of Zurich, to the Liebeault-Bernheim views of hypnotism, German and French medical literature has received a continually increasing number of contributions to this subject.

The peculiar views taught at Nancy by the physicians above referred to are, in many respects, antagonistic to the ordinarily accepted utterances of Charcot and his pupils at Paris.

Dr. C. L. Dana, in a recent clinical lecture reported in *The North Carolina Medical Journal*, June, 1888, calls attention to these views, and indicates the way in which they may be, perhaps, practically and usefully applied by regular physicians—and by regular physicians alone.

The peculiarities of the Nancy school are these: They do not believe in the three phases of hypnotism—lethargy, catalepsy, and somnambulism; hysterical patients, such as were used by Charcot, are not good subjects for studying hypnotic phenomena. The hypnotic state is not a pathological, but a normal, nervous condition, allied very closely to sleep; persons may be hypnotized in very varying degrees of intensity, in some of which the subjects hardly seem to be in a different state from the normal one. The method of hypnotizing patients should always be by simple suggestion. The old method of using brilliant objects, fixing the patient's eyes, etc., is faulty, and likely to cause injury. The new method, properly applied, is harmless.

This "suggestive method," as taught by Liebeault and Bernheim, is described by Dr. Dana as follows: The patient is placed in a chair in front of the operator. The operator then talks to the subject in a firm and confident voice, assuring him that he will go to sleep in a short time, telling him to make no resistance—that his sleeping will be natural, that nothing will be done to worry or fatigue him, that he will dream pleasant dreams, that he will wake up feeling better; then that he is feeling drowsy, his eyes are heavy, objects look confused, the lids are falling, they are closed—in a moment more the patient goes off to sleep. All this may require some little time—five to fifteen minutes. It may fail the first time and succeed the second. It is not always possible or necessary to put the patient to sleep; the effect may be gained short of this.

Professors Bernheim and Liebeault found that, by their method, they could hypnotize ninety per cent. of their patients. Forel, after studying the work at Nancy, said he had been able to hypnotize at least eighty per cent. of his patients. The class of persons that are hypnotized does not include necessarily the hysterical or weak-minded. Indeed highly excitable, hysterical persons, and insane persons are rather less easily affected by this method than those with a sounder nervous constitution.

The proportion of persons of all ages found to be hypnotizable by Beannis was about eighteen or twenty per hundred. Children up to the age of fourteen are very susceptible. After the age of fifty-five susceptibility lessens. Men are almost as easily affected as women; but persons of a docile mind, and those trained to some degree of mental discipline and capacity for submission, such as soldiers and artisans, are more sensitive.

The class of cases in which good results have been reported are rheumatism, neuralgia, alcoholism, morphine habit, various functional nervous diseases, and amenorrhœa. It has been applied also in the treatment of extremely refractory children.

The particular point made by the lecturer was that Bernheim and others in France had been working out on a rational basis the same art that the mind-curers in this country have been empirically applying. In other words, mind-curing and the "suggestion" of Bernheim are the same thing; the docile patients who sit about the parlors of mind-curers, if affected at all, are really experiencing hypnotism in some of the minor grades described by the French authors. Practising physicians, no doubt, in many cases cure unconsciously by "suggestion." They should, however, it is thought, know the scientific basis of their therapeutics, and perhaps extend its practical application. Dangers exist probably, however, even when suggestion is applied as directed by the Nancy school. This the report made to the Royal Academy at Brussels shows. Suggestive medicine and hypnotism, therefore, are measures to be tried carefully, and only by competent and responsible persons. Travelling mesmerizers should be prohibited by law, and parlor experimentation among the laity rigidly discountenanced. The regular physician, however, may, we are told, if he understands the "new hypnotism," take away the ground from under the mind-curer's feet, by a reasonable and careful application of "suggestion."

It is but just to add, as stated in the article quoted, that some of the observations now put forth by Bernheim were made and published some five years ago by physicians of this city, especially by the late Dr. Beard.

Sir Morell Mackenzie and the Report of the German Physicians.—A firm of London publishers recently wrote to Dr. Mackenzie informing him that a translation of the report of Dr. Bergmann and others on the case of the German Emperor had been offered them for publication, and asking whether he would object to the publication. They received the following reply: "I am much obliged to you for your courteous letter. I am not surprised to find that Messrs. Shenk, the Imperial publishers, of Berlin, are offering their thoroughly professional and strictly veracious publications for sale in the London market. I do not think, however, that any respectable publisher in this country will jump at securing the honor and profit necessarily contingent on the reproduction of the edifying document. But should any enterprising firm, emulous of the fame attaching to Curl in the past and Catnach in the present century, be found to swallow the delectable bait, I shall not shrink from a prompt vindication of my professional reputation through the medium of the law courts."

News of the Week.

American Orthopedic Association.—The following is a list of the papers to be presented at the meeting in Washington, September 18, 19, and 20, 1888: "The Modern Treatment of Chronic Joint and Spinal Disease," by Newton M. Shaffer, M.D., New York; "Immobilization in Articular Disease"—Report on the treatment of club-foot by means of the Thomas wrench, or the "T. T," by V. P. Gibney, M.D., New York; "Mechanical Treatment of Senile Coxitis," by Henry L. Taylor, M.D., New York; "A Practical Point in the Treatment of Pott's Disease of the Spine," by A. B. Judson, M.D., New York; "An Efficient and Inexpensive Method for the Mechanical Treatment of Pott's Disease," by C. F. Stillman, M.D., New York; "Rest, in the Treatment of Chronic Joint Diseases," by John Ridlon, M.D., New York; "Acute Epiphysitis in Infants," by Dillon Brown, M.D., New York; "Remarks on Lateral Curvature and its Early Treatment," by Samuel Ketch, M.D., New York; "Osteotomy for Anterior Tibial Curves," by De Forrest Willard, M.D., Philadelphia; "Description of an Apparatus for Measuring any Inequality in the Lengths of the Lower Extremity," by T. G. Morton, M.D., Philadelphia; "Hæmatoma Oris, as a Sign of Injury to the Spine in the Superior Cervical Region," by Benjamin Lee, M.D., Philadelphia; "Two Knee-joint Excisions," by A. J. Steele, M.D., St. Louis, Mo.; "Report on Morton's Operation for the Immediate Reduction of Club-foot," by H. Hodgen, M.D., St. Louis, Mo.; "Femoral Osteotomy," by Ap Morgan Vance, M.D., Louisville, Ky.; "A Case of Reflex (?) Valgus," by George W. Ryan, M.D., Cincinnati, O.; "Remarks on the Operative and Mechanical Treatment of some Joint Diseases and Injuries, with especial Reference to the Hip-, Knee-, and Elbow-joints, with Illustrative Cases," by W. R. Whitehead, M.D., Denver, Col.; "Analysis of Treatment of Seventy Cases of Club-foot," by E. H. Bradford, M.D., Boston, Mass.

Lewis Hall Sayre, *Secretary*.
285 Fifth Avenue, New York.

The Mississippi Valley Medical Association will hold its meeting at St. Louis, on September 11th, 12th, and 13th. The first day will be given to the discussion of abdominal surgery; the second, to infant feeding and some obstetric subject; the third day will be taken up with volunteer papers and some neurological subject. The society extends a cordial invitation to all members of the profession.

J. Lucius Gray, *Secretary*.

Puncture of the Retina for Detachment.—Dr. T. Y. Sutphen, of Newark, N. J., writes: "In the report of the Ophthalmological Society in The Medical Record of August 4th, in the abstract of my paper, on page 138, the last sentence should read: 'Provided the point be so directed that the wound in the retina shall *not* be directly opposite the scleral puncture.' I considered this an important feature of the operative procedure, and laid stress upon it in the original."

Dr. John F. Dunphy, of this city, died on August 12th, of Bright's disease. He was a graduate of Georgetown College in 1873, and was thirty-eight years old at the time of his death.

Yellow Fever is reported to be epidemic in Jacksonville, Fla. As there remain still several weeks before the end of the hot season, considerable alarm is felt in the neighboring towns lest the disease extend, and several towns have established a quarantine against the infected city.

Dr. Ludwig Julius Budge, professor in the Anatomical Institute in the University of Greifswald, died recently, at the age of seventy-seven years. He began life as a practising physician in Altenkirchen, but after a few years gave up regular practice, which was little to his taste, to engage in anatomical and physiological studies, which he prosecuted with zeal to the end of his life.

A Therapeutical Congress will be held in Paris, during the Exposition, at the end of July or beginning of August, 1889. It is to be under the management of the French Therapeutical Society. The annual meeting of the French Association for the Advancement of Science will be held at the same time and place.

Uroleucic Acid is the name of a new acid isolated from the urine by Dr. Robert Kirk, in cases of alcaptonuria. When boiled with Löwe's bismuth test-solution it reduces the bismuth, throwing down the black suboxide and darkening the urine. This is different from another substance, alcapton, found by Bödeker in alcaptonuria.

Absence of the Mammary Glands.—A curious case is reported by Dr. W. Wylie in the *British Medical Journal* of August 4th, of complete absence of both mammæ in a woman aged twenty-one. The girl was not married, but had given birth to a child three months before. The labor was natural, and no pain or uneasiness of any sort was occasioned by the absence of milk. A small mole exists near where the right nipple should be found, but there is no nipple on the other side, nor is there on either side a trace of anything at all suggesting a mammary gland.

A Death from Seasickness occurred recently on a Scotch steamer. The patient was a child aged eight, who became most severely sick, and the sickness finally culminated in a convulsion during which she died.

The Lettsomian Lectures of the Medical Society of London will be delivered next year by Dr. Gowers, F.R.S., who will take for his subject, "Diseases of the Nervous System due to, or related to, Syphilis."

Prince Louis Ferdinand, of Bavaria, has passed the final medical examination qualifying him to practise as a physician. He is the second member of his family who has joined the medical profession.

The Third Congress of Russian Physicians will be held in St. Petersburg in the early part of January, 1889 Connected with it will be an exposition of drugs, instruments, and various appliances for the sick.

The Foochow Medical Missionary Hospital.—The sixteenth annual report of this institution presents evidences of its continued usefulness. During the year five thousand and seventy-three patients were treated, and four hundred and ninety surgical operations were performed. The class of medical students numbers six. Dr. Henry T. Whitney is the physician in charge of the hospital and dispensary.

Society Reports.

FRENCH SURGICAL SOCIETY.

Stated Meeting, July 18, 1888.

(Special Report for THE MEDICAL RECORD.)

M. POLAILLON, PRESIDENT, IN THE CHAIR.

M. **TERRIER** read a paper on the treatment of

HAMMER-TOE

by resection. This method had been practised successfully by MM. Brun and Charles in two cases previously reported by them. In the first case there was a deformity of the second toe, thought to have been caused by a badly fitting shoe. The toe was flexed so strongly that the patient walked on its dorsal surface. M. Brun opened the joint and resected the head of the second phalanx. The wound was immediately closed, no drainage being provided for. The patient made a good recovery and the function of the foot was perfectly restored. The patient of M. Charles was a woman, aged thirty. The same operation was performed, and though the toe was not perfectly straightened the woman was able to walk well and without discomfort. A similar operation was performed subsequently by M. Cohen. Two instances were also reported by M. Schwartz. In these cases, however, the method followed by Williams and Anderson was adopted. This consists in making a longitudinal, instead of a transverse, incision, and possesses the advantage of allowing the removal of the callosity and of the bursa lying over the most prominent part of the deformed toe. The author then reported a case of his own, occurring in a young girl, who had a congenital hammer-toe which had been aggravated by a badly fitting shoe. He resected the ends of both bones by the cutting pliers, inserting a drainage-tube. The latter was removed on the third day, and on the tenth day recovery was complete, the patient being able to walk well. Since then he had simplified the operation by discarding the drainage-tube as well as the plantar splint. In the time that had elapsed since his previous report he had performed

CUNEIFORM OSTEOTOMY

successfully in eight cases. One of these was in the person of a physician, aged thirty-four, who had congenital hammer-toe of the four smaller toes of each foot. The deformity had increased progressively since the patient's sixteenth year, although it had not incapacitated him from serving his term in the army. Within a short time, however, it had grown rapidly worse, and walking had become very painful, especially in the morning. Cuneiform osteotomy was performed, and the patient was subsequently able to walk as well as if he had never had anything the matter with his feet. Blum had advised amputation in these cases, but the speaker believed osteotomy to be far preferable.

M. **TERRILLON** had performed osteotomy in five cases with excellent results. The operation was a very simple one, and was, he thought, strongly to be recommended for the relief of this crippling deformity.

M. **DESPRÈS** favored

AMPUTATION OF THE TOE

in advanced cases of the deformity when ulceration existed. If there was no ulceration he thought it was better to leave the patient alone. He amputated the first phalanx in continuity, and the result was always a definite cure. When resection was resorted to, a perfect correction of the deformity was not always secured, and he had seen rebellious cicatricial ulcerations persist, as in a case operated on by the method advocated by the reader of the paper, in which the speaker had subsequently performed an amputation. The case of the young physician reported by M. Terrier was one not of hammer-toe but of pes cavus, a condition well described by Duchenne, of Boulogne.

M. **TRÉLAT** thought that the procedure to be adopted should vary according to the age of the individual. In adults he preferred osteotomy, as advocated by M. Terrier, but he did not discard the plantar splint, which he thought served a very useful purpose in maintaining the toe in its new position. In children the deformity may generally be overcome by electricity, manipulations, and the application of a retentive apparatus. The last speaker was in error in assuming that the condition of multiple hammer-toe was identical with pes cavus, for he had seen cases in which all the toes—particularly the third, fourth, and fifth—were bent, but in which flat foot existed.

M. **SCHWARTZ** had seen a case of double hammer-toe, in a child five years old, cured definitely by means of a plantar splint, with tapes attached, which passed over the affected toes, holding them flat. In another case, occurring in a young woman, aged eighteen, this treatment was ineffectual, and he was obliged, subsequently, to resort to osteotomy. The results of the operation were all that could be desired.

M. **TERRIER** said that the discussion had brought out reports of twenty-three cases in all, treated successfully by resection. He had never been called upon to treat any cases in young children, but had had an adult patient upon whom the method referred to by M. Trélat had been tried in childhood without success. He thought the law of exemption from military service was badly executed, for the physician whose case he had reported should not have been made to serve.

M. **CHAUVEL** said that the regulations exempted recruits in whom the deformity was so far advanced that the nails rested on the ground.

M. **DESPRÈS** thought that the speakers had confused many varieties of deformity of the toe under one name. Besides hammer-toe there was a similar but distinct deformity known as *orteil en chien de fusil*, which was a very different affection, and not to be confounded with the former.

M. **TERRILLON** reported a case of

CHYLOUS ASCITES

occurring in a woman, aged thirty-seven. Eight years ago she had noticed that the abdomen was increasing in size, while at the same time she began to emaciate rapidly. Paracentesis was performed two years ago, and a quantity of a light chocolate-colored fluid was withdrawn. No diagnosis was made at the time. One year later a second puncture was made and the same sort of fluid was removed. Soon after this the patient came under the author's care, and on examination he detected the presence of a tumor enveloping the uterus. The patient's condition was very serious, and M. Terrillon determined to perform

EXPLORATORY LAPARATOMY,

thinking that the tumor was ovarian. The incision gave exit to about eight pints of chylous fluid, having a specific gravity of 1.021, alkaline reaction, and the color of café-au-lait. It contained a large proportion (nearly four ounces to the pint) of albuminous and fatty matters. On the left side of the uterus was found a small fibroid tumor, involving the broad ligament. The peritoneum was reddened and velvety, and bled easily. The abdominal wound was closed, and the patient recovered from the operation, but the fluid was quickly reformed.

Two theories in explanation of this rare condition have been advanced. The first, propounded by Weill, Debove, and others, is that the chylous fluid results from a transformation of pus, the primary condition being a suppurative peritonitis. The speaker thought this view was hardly tenable, for the fluid contained much more fat than pus, and he inclined rather to the opinion that it was due to ruptures in the lymphatic vessels. He had seen a case of chronic suppurative peritonitis in at old woman at the Salpêtrière, in which the effusion presented much the same appearance as that seen in chylous ascites, but microscopic examination showed the presence of but a minute quantity of fatty material. In a case reported by Straus, small openings in the lymphatic vessels were plainly to be seen. In his own case he had been unable to discover these openings, although he had searched for them. He did not believe the presence of the small fibroid tumor had anything to do with the origin of the chylous ascites.

M. Bouilly spoke of

THE RELATION BETWEEN ASCITES AND ABDOMINAL TUMORS,

which was, however, very obscure as yet. He had seen one case, occurring in a woman, aged forty-five, in which he thought the effusion was due to the presence of a malignant growth of the ovary, but on operation the ovaries were found to be normal, while the tumor was a smooth uterine fibroid. The abdomen contained nearly two gallons of fluid, and the peritoneum was so injected that a general hemorrhage occurred from its surface after the pressure of the fluid was removed.

M. Quénu admitted that the

PATHOGENESIS OF ASCITES

was still a vexed question, but he believed that the cause lay in a peculiar condition of the peritoneum, which was found covered with inflammatory granulations, looking as if sand had been strewn over it, and suggesting cancerous or tubercular disease. He had examined these little granulations, however, and had found them possessed of no special histological characters. This alteration in the peritoneum was often found associated with ruptured ovarian cysts, but it had also been observed in connection with solid tumors of the ovary or uterus.

M. Lucas-Championnière said that the presence of ascites in connection with an abdominal tumor was strongly presumptive of the malignant nature of the latter. It was true that ascites was met with occasionally in cases of benign tumors, but such instances were very exceptional, and no satisfactory explanation of them had ever been made. He had seen two such cases in which there was an enormous development of lymphatic vessels in the omentum.

M. Terrier said that ascites might occur in simple chronic peritonitis, and he had seen it in connection with very small tumors. There was still much to be learned of the pathogenesis of ascites, and he thought the study of the relation between hydrocele and changes in the epididymis might throw some light on the subject, since hydrocele and ascites were similar conditions.

M. Terrillon said that he had referred only to chylous ascites in his paper, and had not purposed opening a discussion on the relation of ascites to abdominal tumors. Concerning serous effusions, however, it was well to bear in mind the fact that they were found associated with two distinct conditions of the peritoneum. In one case the peritoneum was reddened and velvety in appearance, while in the other it was pale and showed no traces of inflammatory change.

M. Le Dentu reported a case of

TOTAL EXTIRPATION OF THE LARYNX.

The patient was a man suffering from some affection of the larynx, but the diagnosis was not certain, and lay between syphilitic œdema of the glottis and carcinoma. Intercrico thyroid laryngotomy was first performed for relief of the threatened apnœa. Soon after this the growth began to increase rapidly, and the larynx became adherent to the skin, so that the question of diagnosis was no longer uncertain. A preliminary tracheotomy, as low down as possible, was performed, in order to accustom the patient to the presence of the cannula and to breathing through it. The operation of removal of the larynx was performed in the usual way, but it was found that the neoplasm had invaded the œsophagus, necessitating the employment of the thermo-cautery to remove the diseased part. Notwithstanding this complication, however, the immediate results of the operation were good. There was some slight pulmonary congestion, which disappeared after the application of a few cups. At the end of about a month, however, a recurrence of the disease took place in the floor of the mouth, and the patient died after three months of great suffering. The operation had been attempted too late, but the patient would not at first give his consent to the extirpation of the larynx, even after the diagnosis of cancer had been established. The speaker thought, however, that the fact of a recurrence of the disease in this case argued in no sense against the wisdom of the operation in laryngeal carcinoma. It was true that the mortality of the operation itself was double that following tracheotomy (forty per cent. in the former, and twenty per cent. in the latter), but the average period of survival is greater in the former than in the latter. The operation would therefore seem to be a justifiable one.

M. Bouilly exhibited the patient upon whom he had performed

RESECTION OF THE INTESTINE,

and whose case he had reported at the last meeting of the Society (page 161). Previous to the operation the patient had weighed but seventy pounds, but since then she had gained rapidly, and now weighed ninety-two pounds, her appetite and strength keeping pace with this improvement in avoirdupois.

M. Berger presented a patient upon whom he had performed a

RESECTION OF THE ANKLE,

in the treatment of tubercular disease of the astragalus. Bending of the foot outward had been prevented by the insertion of an ivory peg, which was removed at the end of about two months after the operation. The results of the operation were all that could be desired, the wound having closed readily and completely, and the disease having been thoroughly eradicated.

The Society then adjourned.

Mastoid Disease in Minnesota.—It will be remembered that the late Mr. Roscoe Conkling developed his fatal mastoid disease soon after protracted exposure in the "blizzard" of March last. Dr. Frank Allport, of Minneapolis, Minn., writing in the *Northwestern Lancet*, says that during a practice of five and one-half years in that city, and with a total number of seven hundred and sixty-two ear cases, he has opened the mastoid twenty-five times, always finding pus. Comparing this proportion with that observed in other cities, Dr. Allport concludes that the climate of Minneapolis, with its enormous extremes of temperature from winter to summer, has a special tendency to produce mastoid disease, as it has toward catarrhal affections generally.—*Boston Medical and Surgical Journal.*

Water and Obesity.—A physician of Erlangen, Dr. Lorenzen, experimented with himself for the purpose of seeing the effects of imbibition of water upon the bodily weight. For four years he indulged in the not ascetic task of drinking two gallons of beer daily, and discovered the remarkable fact that he had increased his weight seventy-eight pounds. On stopping the ingestion of water (beer) he reduced his weight fourteen pounds in seven days. Dr. Lorenzen's experiments are being performed daily by a large class of our esteemed Teutonic citizens.

Corpses as Parlor Ornaments.—A Pittsburg physician is said to have invented a process of preserving human bodies by compression with steel rollers and hot presses. A full-grown body can be reduced to a small size, about 12 × 15 inches; it can be made to assume any shape, and thus form an ornament for the parlor. He has on his centre-table the body of a child in the form of a cross. It is entirely odorless and resembles marble.

Correspondence.

DUBLIN LETTER.

(From our Special Correspondent.)

GYNECOLOGICAL WORK IN IRELAND—ADDRESS ON OBSTETRICS AT THE MEETING OF THE BRITISH MEDICAL ASSOCIATION—ELECTROLYSIS IN THE TREATMENT OF UTERINE FIBROIDS—MANAGEMENT OF THE THIRD STAGE OF LABOR—SIR FIELDING OULD.

THAT branch for which Dublin is so noted, obstetric medicine, will form the greater part of this letter.

Dr. Arthur V. Macan has recently removed the uterus by vaginal extirpation and tied both ureters, with a good result. The operation was quite favorable in its results and the recovery rapid. Dr. Macan removed the uterus for supposed malignant disease, but after removal the most competent microscopists could find no trace of cancer. This brings up a fact with which the most competent have found themselves confronted on several occasions.

Dr. Kinkead has recently had a number of cases under his care where the hymen has persisted after frequent intercourse, and in several instances in prostitutes of the most notorious character.

During the past year at the Rotunda, Emmett's operation has been performed but once. It is strange with what stubbornness this operation is resisted on this side of the water. Fifteen abdominal sections were made at the Rotunda during the year, and only one case of tubal disease required an operation. There were two cases of extrauterine pregnancy, one of which died.

Dr. Lombe Atthill, the well-known obstetrician and gynecologist of Dublin, and for so long the very acceptable master of the Rotunda Hospitals, is being much talked of as a candidate for the presidency of the Royal College of Physicians of Ireland.

Dublin obstetrics and Dublin obstetricians have been highly honored of late, first, by the selection of Dr. A. V. Macan as president of the Section on Obstetrics at the Dublin meeting last year and in his very satisfactory manner of carrying out his duties in this chair; and, second, by the choice as president for the Glasgow meeting this year of the well-known obstetrician, Dr. Thomas More Madden, also of Dublin, and formerly master of the Rotunda Hospitals.

To Sir Fielding Ould, the second master of the Rotunda Hospitals, is credited the first employment of version as a substitute for craniotomy in 1752. It was revived and published more extensively by Dr. McClintock a century later. The revival of the use of the forceps, the prophylaxis of the post-partum hemorrhage, and many other important improvements in the management of childbirth and the puerperal state, the introduction of which is claimed elsewhere, have also emanated from this same practical school of midwifery.

It has been your correspondent's privilege, in consideration of the great length of time required to cross the Atlantic, to have an ante-partum glance at the address of the president of the Section on Obstetrics at the Glasgow meeting of the British Medical Association, Dr. T. More Madden, of Dublin. Dr. Madden makes quite a complimentary review of the history of Scotch obstetrics, in which he speaks in the highest terms of Young, Hamilton, Smellie, Hunter, Houstoun, Lizzars, Simpson, Duncan, and Keith. He then reviews, in a somewhat briefer strain, the work and glory of the Dublin school of obstetrics.

The progressive treatment of midwifery practice received consideration. He thought that it had been very great during the last few years. The writings of Dr. Priestly have freed from much of their former obscurity and difficulty the pathology and treatment of intrauterine death. The present control of epidemics of puerperal septicæmia and the treatment of the same disease are matters of great congratulation. Improved methods in the treatment and prevention of post-partum hemorrhage have saved many lives. The throes of labor are much mitigated by the employment of comparatively safe anæsthetics, such as have been used by the eminent writer for the past twenty years; viz., two parts of ether and eau de Cologne with one part of chloroform. That period of protracted parturient suffering which, as a student, he had often seen allowed to continue for forty, fifty, or even eighty hours, is now safely abridged by judicial instrumental assistance. The use of child-destroying instruments has been decreased in exact proportion to the increasing employment of the forceps. The main reason why craniotomy instruments have remained so long in use is the failure of most midwifery practitioners to sufficiently recognize the compressive powers of the long forceps. He then exhibited two instruments; the one can be used in nine-tenths of all cases, viz., where uterine inertia exists in the second stage, the other for cases of difficulty from disproportionate flattening of the pelvis.

The recent progress in gynecology he thought even greater than that in obstetrics. He mentioned the advantages derived from rapid and safe dilatation of the cervix uteri in diagnosing and treating disease. In the pre-antiseptic days the wonderful results which have been realized in laparotomy operations could not be anticipated. Especially is this so in regard to ovariotomy and cancer, and even peritonitis. Ovarian displacements, the bearing of cervical lacerations on pelvic pathology, the diagnosis, importance, and curability of diseases of the uterine appendages, such as hydro- and pyo-salpinx, were formerly practically ignored by gynecologists. Prejudice and fashion have as great a play in gynecology, if not greater, than in any other department of medicine. He could not agree with those who opposed the admission of women to the practice of the art among those with whom they were so especially fitted. He thought that, in this age, women who preferred to be treated by women should be allowed that privilege. He doubted if the lady doctors would ever replace the ruder sex in the general estimation of their sisters, yet there were fields of great usefulness for the female practitioner in India and other Oriental countries, and he was in favor of the admission of women into the British Medical Association. Foremost among the signs of progress in gynecology are the results of abdominal surgery in the treatment of abdominal tumors. He urged the expediency of a fair trial of less serious methods of treatment before resorting to the extirpation of the uterine appendages. The operative treatment for uterine fibromata, which he considers to be quite a debatable question, received a good share of his attention.

Treatment of uterine fibroids by electricity he considered as the most promising method of dealing with this trouble. His own experience had been considerable, and had been most satisfactory in the arrest of hemorrhage. He had observed no entire cure, yet he had seen a subsidence of the tumor to a marked degree, even after six weeks or two months of treatment. In his cases he used Apostoli's method as nearly as he could. If the results attained by Apostoli are confirmed by others, as he hoped they would be, then we may well congratulate ourselves on having at last arrived within sight of the long-sought-for safe and effectual curative treatment of uterine tumors.

His résumé, he thought, afforded a sufficient vindication of his branch of medicine from the aspersions which had been poured upon its followers. This is no narrow specialism, and should rank high in the profession of medicine, the great object of which is the prolongation of life and the relief of every form of suffering.

External palpation in the diagnosis of pregnancy receives much merited attention at Dublin. They determine the fact of pregnancy, period, size of the child, condition of the bladder, axis of the uterus, condition of the abdominal walls, abnormalities of the ovaries, such as twins, excessive liquor amnii, hydrocephalus, anencephalus, hydatid mole, and frequently the life or death of the fœtus. It directly leads to the practice of external turning, renders the finding of the fœtal heart simpler, often tells whether the pelvis is contracted or not and the amount of disproportion between the head and the pelvis. Such accuracy is attained that they are often able to feel the arm of the child growing out from the shoulder and to get the fingers in the groin, and occasionally the elbow is palpated. A hydrocephalic head has been readily made out, and in one case anencephalus. In some instances the cord has been felt crossing the child's back, and the placental site has been determined by the fingers being lifted off the child and the outlines of the body being rendered indistinct. To make this possible, the placenta must be implanted on the anterior wall and the conditions for palpation favorable.

In the third stage of labor, as soon as the child is born the left hand is placed on the fundus, the ulnar edge pointing toward the vertebral column, with the palm of the hand looking directly in the axis of the uterus. The eyes are carefully wiped and a finger passed in to see if the cord is passed around its neck. If the uterus fails to act promptly, or the child shows symptoms of defective aeration, pressure is made on the fundus, which is generally sufficient to expel the child. If not, gentle pressure is exerted on the head, which presses it backward toward the perineum till the anterior shoulder, with a well-marked jerk, passes the pubes, and delivery is terminated by pressure over the fundus uteri. The left hand follows down the fundus as the child leaves the uterus, expelling any liquor amnii which may remain. The head remains in the same position as before the child was born. The accoucheur rotates the hand so that the fingers irritate the posterior and lateral sides of the uterus, especially the insertion of the round ligaments. Improperly done, this pressure may do harm instead of good. The fundus may be deflected to one side, generally the left, and if pressure be made in the median line this flexion is still more increased, folding the uterus on itself and pressing toward the fundus rather than toward the os. By means of his hand the attendant keeps himself posted, by watching alternate relaxations and contractions, as to whether the uterus is becoming widely distended with blood or not. The nurse ties the cord as soon as pulsations have ceased, and the medical man never loses his grip on the uterus. If in a state of asphyxia, the physician directs his attention to the child, and the nurse follows the uterus. If there is a tendency to post partum hemorrhage on the part of the mother and asphyxia in the child, the physician must be bound, under these delicate circumstances, to look after the welfare of the mother. No accumulation of blood taking place in the uterus, gentle friction is used every fifteen minutes, and firm pressure is made on the fundus in the axis of the brim and at the acme of the contraction. This nearly always expels the placenta from the uterus and the vagina. The hand is still kept over the uterus till there is no danger of a recurrence of hemorrhage, when the binder is applied and the woman turned over on her back. This has been the method employed in the Dublin Lying-in Hospital since the mastership of Dr. Joseph Clark, 1786-93. In the words of Dr. Collins, a duty of paramount importance was to press the placenta out of the uterus during the third stage of labor. This method should be called by the name of the city in which it first saw light, the Dublin method.

That reputation for which the Dublin school of midwifery is so noted is due largely to the Rotunda and her students, who number now about seven thousand. These are doing good work, not only in the British Isles, but also in the colonies, America, France, Germany, and other countries. The annual number of women delivered at the hospital is about one thousand two hundred, and in the externe department about one thousand six hundred. Laceration of the perineum of more than three-fourths of an inch is treated at the Rotunda by douching out the vagina with an antiseptic solution and suturing immediately with silk or catgut, using the continuous suture with the latter. The stitches are inserted deeply, so as to bring the whole of the torn surfaces together and prevent the entrance of lochia into the wound.

Corrosive sublimate for the hands, 1 to 1,500, and for intrauterine injection, 1 to 4,000, has almost entirely taken the place of carbolic-acid solution. In cases of considerable hemorrhage, suspected renal mischief, or great corpulence, where absorption is great and mercurial poisoning is feared, 1 to 100 or 1 to 80 solution of carbolic acid is used. Evaporation of carbolic acid in the wards is now discontinued, as is the use of iodoform pessaries, excepting in cases where there is much fetid discharge after first washing out the uterus. The napkins used are soaked in a sublimate solution, 1 to 500–1,000, and wrung out before being applied to the vulva. The mortality from any form of septic infection is $\frac{52}{100}$ per cent., or 1 in 189.6. Eighty-five per cent. of the cases do not exceed the maximum physiological temperature, 38° Centigrade, or 100.4°F.

Forceps cases are about six per cent. of all cases. Of these there is a mortality of about three per cent. Axis-traction forceps are used in a large proportion of cases.

Infantile asphyxia is treated after the method of Schultze. The incubator is used with a considerable degree of success with asphyxiated children; also those whose circulation is bad.

The prophylactic treatment of ophthalmia neonatorum is never adopted until the disease is manifest. Nitrate of silver solution, eight grains to the ounce, is then applied to both eyes, even though but one is affected. The proportion of these cases is 1 to 100.

Hour-glass contraction is believed to be due to pressure on the ring of Bandl, which causes the circular fibres to contract tonically and may imprison the placenta or a part of it. The difficulty is sometimes removed by douching the uterus with a hot sublimate solution.

When the placenta is adherent, the hand is passed into the uterus, first being made antiseptic.

Careful external examination is recommended to be made of every pregnant woman a fortnight before the expected confinement, and thus determine whether malposition or conditions favoring it are present.

In the case of retained membranes, gentle traction is made on the part left behind; as a rule, the ligature is tied on the retained portion as near as possible to the vulva. It is then twisted into a sort of a rope, whereby its chance of breakage is lessened. If a large amount is left behind the douche is often used, in the hope that a portion or all of it may be brought away.

The bimanual is made with the patient lying on her back, contrary to the general practice in Great Britain, and great stress is laid on this position.

The Rotunda Lying-in Hospital is the oldest of its kind in the British Isles and the oldest but one in the world. It was founded by Dr Bartholomew Mosse, who experienced many vicissitudes in his noble endeavors, and his heroism in the face of difficulties, slander, and poverty is worthy of all honor. In establishing the admirable institution, which freely receives within its walls all who have poverty for their plea and the pangs of approaching maternity as the grounds of their request, he plunged himself deeply in debt, and was arrested in Wales when returning from London, and thrown into debtors' prison. His successor was Fielding Ould, who was afterward knighted. Upon this occasion some contemporary wrote:

> "Sir Fielding Ould the sword of knighthood gained,
> For saving ladies' lives in childbed pained."

Also another, who thought the rank conferred was not exalted sufficient:

> "Sir Fielding Ould is made a knight,
> He should have been a Lord by right;
> For then each lady's prayer would be—
> 'O Lord, good Lord, deliver me.'"

McClintock affords to him the honor of attending the Countess of Mornington at the birth of the Duke of Wellington. He attained considerable prominence while still comparatively young, and was described by a jealous critic as "the youngest surgeon practising midwifery in the city."

The R. C. P. I. refused to examine him for the degree of Trinity College, on the ground that the practice of obstetrios was degrading to the dignity of the profession of medicine. This absurdity was shown up in its ridiculous light by Gilborn, who wrote:

> "The College him a Fellow would announce,
> Condition this, to midwifery renounce:
> Renounce but sooner he would his right hand,
> Than from the service of the Fair disband.
> Why may not a doctor who would chuse
> For man's relief his total knowledge use,
> Or does one portion of Apollo's trade
> More than the rest his votaries degrade?"

LETTER FROM FREIBURG, GERMANY.

(From our Special Correspondent.)

MEDICAL PILGRIMS TO EUROPE—ADVANTAGES OF THE SMALLER UNIVERSITIES—THE STUDY OF GYNECOLOGY AT FREIBURG—THE DIRECTOR OF THE FRAUENKLINIK—OPERATIVE METHODS AT FREIBURG.

FREIBURG, July 30, 1888.

THE annual stream of Americans bound Europeward carries with it a yearly increasing number of physicians. They are of all ages and degrees. There is the recent graduate, fresh from his alma mater, characterized by his obtrusive readiness to give you points on everything. He is generally engaged on a self-inflicted mission of instruction to his benighted European confrères. Between this entertaining specimen of the genus medicus and the hoary-headed "old stager," on his "first trip across," there is every conceivable intermediate variety of practitioner, including the "professor," who may seem youthful, but whose dignity and title are not to be trifled with. It is noticeable that the older medical people are commonly quite as eager to "get points" as their juniors are to dispense them.

But, tyro or man of experience, with few exceptions they all drift toward the large cities, if they are in search of medical instruction. This prevalent practice I wish to caution your readers against following. A residence of nearly five years at various European university towns had long ago taught me that time is much more profitably spent at the smaller schools than at the great and famous "medical centres" of the capitals.

This opinion has just received added force from a residence at Freiburg of five weeks. The man who has travelled all the way from San Francisco to Vienna, in order "to see Billroth operate," is very apt to be speedily undeceived when he gets there, and to regret his trip. I venture to assert that no practitioner, old or young, will regret having spent some time at this university. Is it not time to remember, once for all, that overcrowded lecture-rooms are not conducive to profitable instruction? The small-fry hangers-on of the "large city" clinics will readily promise you unbounded advantages in exchange for a generous supply of the coveted American dollar. But he who has had access to the charmed inner circle of these "teachers" will agree with me in saying, that the "American medical lamb" is a fully recognized institution there. (Moral: To preserve your fleece, don't be a lamb.)

At the smaller universities you are treated fairly and squarely, and I am confident that for considerably less money you can there get considerably more useful information. Lest my meaning be misunderstood, I must add that this applies to the study of medicine in general. Those who visit Europe only to "see many cases" in some narrow special line will, of course, find more material at Paris, London, Berlin, or Vienna than at the smaller universities, like Freiburg, Halle, Würzburg, and others.

THE STUDY OF GYNECOLOGY AT FREIBURG,

which formed the chief object of my visit here, can be pursued in a most profitable manner at this university. An adequate knowledge of the German language is quite essential, however; and it is eminently unsatisfactory to attempt to learn German by listening to Professor Hegar's lectures. I mention this particular, because I have known Americans to express disappointment at not learning more "German" at the daily clinical lecture on "gynecology."

The material for scientific gynecological demonstrations, including all kinds of operations, is very ample here. And German clinical material is something peculiar to German soil. You would look for it in vain in America. It is a product of monarchy, with its centralization of power, its awe of office, and the existence of its "lower class brutalized." For the student, the practitioner, and the professor, this state of affairs has its very palpable advantages. To have an unlimited supply of human material that considers it almost an honor to be fully exposed, to be examined again and again, and to be subjected to as much treatment as may be necessary for didactic purposes, what American student and teacher of gynecology will not exclaim: "'Tis a consummation devoutly to be wished?"

And yet, after all has been said on the side of humanity, in opposition to such a system, the fact remains that patients do not fare worse under this rougher usage than they do at home under our system of excessive sentimentality. Another reason why the "material" is so much more pliable and easily instructive here is found in this consideration. Our institutions are compelled to make competitive bids for material. If our professor "acts nicely," and makes a good bid, he gets the case. Here, if the patient behaves, and does not object to occasional rough handling, he gets the professor, *i.e.*, the latter condescends to treat him or her. There is no use in mincing matters—the German system has its decided advantages. But, of course, it cannot be transplanted.

The reputation of the director of the "Frauenklinik" (as the hospital for women is called) has become so widely established that Professor Hegar's private patients include women from all parts of the world, from San Francisco to Constantinople, and from north to south. There is no doubt that his reputation is not the result of accident or influence in high places, as often enough happens over here. It is entirely owing to natural gifts, hard work, and remarkable energy. At home we would call Hegar a self-made man. He is a brilliant surgeon, an astonishingly accurate diagnostician, and, in addition to being an eminent specialist, he has managed to remain a good physician. On top of all this, his intimate knowledge of pathology permits him to speak of the diseases peculiar to women in a way that cannot fail to command immediate confidence.

It was my good fortune to be very well received by Hegar. I was at once made a *de facto* assistant, although, of course, I could hold no official appointment of that kind. And I may as well confess that I had to pocket many a scolding from the professor, who is in some respects rather "cranky." In America, even assistants are not ordered around in quite the perfunctory manner employed by some of the German professors. But this merely *en passant*.

A more thorough method of gynecological examination than is practised here does not exist. The drawback of this method for office practice is, that it almost invariably necessitates complete anæsthesia. Combined rectal and vaginal exploration, with external palpation, is the name given to Hegar's mode of examination. It was like a revelation to me, to learn how much more can be felt in this way than by ordinary vaginal examinations. The ovaries become so accessible, and the uterine ligaments are so distinctly made out, that a nodule as large as a pin's head will scarcely be overlooked anywhere in the pelvis. This leads to extreme accuracy of diagnosis, which I was able to verify again and again.

The system of rigid antisepsis, as practised at Hegar's hospital, deserves some mention, as it is held to have in great measure led to the excellent results recently obtained here. Not to weary you with details, I will simply state that Hegar has just performed sixteen consecutive enucleations of myomatous tumors, of the intraligamentous variety, without a death, and that within a period of less than two years he has done Cæsarean section six times, without a fatal issue. I doubt whether any surgeon can show better results than these. Ordinary laparotomies amount to nearly one hundred annually. The tendency of Hegar is in the direction of altogether discarding the poisonous antiseptics. In place of this he seeks to prevent infection by employing sterilized instruments and dressings, and by extreme precautions as to personal antisepsis, or, rather, asepsis. Sponges have been given up in all laparotomies, and strips of sterilized gauze are employed in place of them. Weak solutions of carbolic acid, iodoform, and chlorinated water are still employed, but in a limited way, and so as to prevent all danger of poisoning from their use.

As the technique of his abdominal sections does not differ essentially from that employed elsewhere, I will turn now to a department of gynecology for which Freiburg has become justly famous, namely, the so-called plastic operations which concern the female genitalia.

And here I must state my impression that Hegar's son-in-law, Dr. Wiedow, if he does not surpass, at least equals his teacher. They both excel in extremely painstaking attention to the minutest details, and the nicety and accuracy of bringing together the damaged and lacerated parts. It is impossible to give a serviceable description of the various operations belonging to this category. To be appreciated and followed, these operations must be witnessed again and again. It may seem like "piling on the agony," but it is nevertheless true that failures after these plastic operations are not known here.

To those of your readers who are not specially interested in gynecology, I can only say that the surgical and medical wards of the Freiburg University afford ample opportunities for profitable study. The surgeon Kraske, formerly Volkmann's assistant, is a wide-awake, go-ahead man. His methods are more conservative, however, than those of many other German operators. Bäumlers, the professor of internal medicine, is almost as well known in America as here. The material in his wards is also very abundant, and well utilized. He speaks English fluently.

Finally, Freiburg, regarded merely as a place of residence, is one of the most charming spots that can well be imagined. Its proximity to the "Black Forest" mountain range, its exceptional climate, pure air and pure water, have combined to render it so attractive that a large colony of foreigners has become permanently established here. It has about 45,000 inhabitants, and it is at present still a cheap place to live in.

Edmund Charles Wendt.

QUININE AND THE TARIFF.

To the Editor of The Medical Record.

Sir: Apropos of your editorial in The Medical Record of July 28, 1888, on "Quinine and the Tariff," allow me to remind you of the following facts: The price of quinine in England has gone down in the last ten years as much in proportion as in the United States; *i. e.*, the percentage of reduction has been the same in the two countries, although there has been an import tax removed in the United States and not in England.

The result in this country of the removal of the tax has been to cause all but one of some seven or eight manufacturers to cease making the drug, and consequently has taken just so much labor away from skilled American workmen.

These firms now buy English and German quinine and put American labels on the packages.

It has also caused us to send over three and one half millions of dollars each year to Europe, which we might as well have kept at home. An import tax sufficient to protect our manufacturers of quinine would not raise the price of a single quinine prescription in any drug-store in the United States. It would make the profits of the wholesale and retail druggists so little less than they are now that they would never notice the difference.

More than that, a small tariff on cinchona-bark would soon develop a new and profitable industry in the United States. We have climate and soil eminently suited to the growth of the cinchona-tree, and there is no righteous and just reason why the United States should not grow and manufacture all the quinine necessary to supply her own market, and thus prevent our sending millions of dollars every year to help support the pauper labor of Europe and India.

Respectfully yours,
D. E. English, M. D.

Mill Burn, N. J.

LOSS OF SEXUAL FEELING AFTER OÖPHORECTOMY.

To the Editor of The Medical Record.

Sir: Despite your recent editorial on the subject, I think the question of necessary loss of sexual feeling after removal of the ovaries must still be considered as *sub judice*, for reasons which will be here stated:

It may be assumed, I think, that if the ovaries become diseased or atrophied to such an extent that their functions are destroyed, the subject is substantially in the same condition as if they were removed. This being granted, we state as a frequently observed fact, that in sterile women sexual feeling is not necessarily absent, and is indeed often exhibited to a very marked degree.

After the menopause sexual desire persists for some years, and not unfrequently is greater than before.

Some years since, I witnessed the removal of the ovaries from a lot of cows and heifers. The operator made an incision in the flank, drew out the parts he wished to remove and cut them off. In one instance, after removal of the ovaries, he again introduced his hand in search of something more. I asked him what he wanted, and he replied that he had failed to remove the "curl," and that that must be cut off too, otherwise you would get a "bulling" heifer, which would be a great nuisance. She would be "wanting the bull all the time and would never be satisfied." He presently found the "curl," which I recognized as the fimbriated extremity of the Fallopian tube, and cut it off.

A Texan horse-breeder stated to me that he had several valuable stallions, and to prevent them being injured by the heels of unwilling mares, he used a common stallion as a "teaser" to test their receptivity, instead of following the usual custom of hoppling the mare. If the mare was found to be in proper condition the "teaser" was led away and the selected stallion put to her. He claimed that a distinct advantage was derived from this practice, in so much as it preserved his valuable stallions from the needless excitement of being taken to mares not quite ready to receive them. I remarked that while this might be all very well for the blooded horse, it must be rather aggravating to the "teaser." He said that he was in the habit of turning over the latter to a female *mule*, who was *always willing to receive him.*

As a female mule is certainly ovarianly inert, whence does she derive her sexual desire?

With these facts and statements before me I must certainly entertain a doubt as to the necessary connection between the ovaries and sexual desire.

Returning to human oöphorectomy, we have evidence that in some cases sexuality is, and sometimes is not, abolished. We further know that in some instances the ovaries are alone removed, and in other instances the Fallopian tubes in addition; but we are not aware that any one has carefully noted whether the loss of desire occurred with equal frequency in both sets of cases.

H. G. Piffard.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 12 to August 18, 1888.

Lauderdale, J. V., Major and Surgeon. Promoted July 28, 1888, to Surgeon, with rank of Major, to rank from July 3, 1888.

Mason, Charles F., First Lieutenant and Assistant Surgeon. Reappointed July 28, 1888, to rank from July 2, 1888. Reported for duty at Fort Washakie, Wyo., August 2, 1888.

Official List of Changes in the Medical Corps of the United States Navy for the week ending August 11, 1888.

Whitaker, H. W., Passed Assistant Surgeon. Detached from the Mohican, proceed home, and wait orders.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 11, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	23	4
Scarlet fever	78	14
Cerebro-spinal meningitis	1	1
Measles	130	12
Diphtheria	94	27
Small-pox	1	0
Yellow fever	0	0
Cholera	0	0

The Sense of Smell is diminished in criminals, according to Dr. Ottolenghi, who made a series of tests upon eighty persons.

Dr. Thomas Wood recently showed before the Obstetrical Society of Edinburgh an experiment proving that the caudal extremity of the fœtus is specifically heavier than the cephalic (*Edinburgh Medical Journal*, July, 1888). In a glass vessel was put a fluid composed of salt water and spirit, of such a density that the fœtus which it contained neither rose to the top nor fell to the bottom, but was suspended in the centre—in fact, the specific gravities of the fluid and of the fœtus were almost, if not entirely, equal. The position which the fœtus assumed, therefore, showed which is the specifically heavier end, and this, as was seen, is the caudal extremity. The fœtus floats in the fluid almost in a vertical position with the head uppermost.

To Facilitate Catheterization in Women.—Dr. S. E. Josephi, of Portland, Ore., writes: "For some time past I have been using a simple device in catheterizing females which adds greatly to the convenience of the operation. As I have not seen any mention of it in books or journals and have not heard of its having been used before, I make this communication, in the hope that it may be of some benefit to the profession. The device consists simply in using a piece of rubber tubing, one end of which is slipped over the distal extremity of the catheter, and the other end dropped into a proper vessel on the floor by the bedside. The ordinary red rubber tubing to be found in any drug-store is appropriate. A piece about four feet long may be used. The tubing being attached to the catheter, the latter is carried over the thigh of the patient in the usual way, the tubing extending from beneath the bedclothes into the vessel. As soon as the catheter enters the bladder the urine flows through the instrument and tubing into the vessel, and upon the flow ceasing the catheter is withdrawn, the residual fluid being allowed to drain from the lower end of the tubing. This obviates the inconvenience of a cup or bowl being held between the thighs of the woman, the leakage or spilling, and the necessary changing for emptying, and replacing a small vessel."

The First Nephrotomy.—In the *Gentleman's Magazine* for August, 1773, appears the following: "Mr. Paul, a surgeon, at Stroud, in Gloucestershire, lately extracted from the kidneys of a woman, by an incision through her back, a rough stone as large as a pigeon's egg, and made an entire cure; it is the first of the kind ever performed in this kingdom."—*Hospital Gazette.*

Dr. Ledyard's Toast.—It is told of old Dr. Isaac Ledyard, a notable character who flourished in Newtown a century or so ago, when there was a frequent passing of the social cup and much drinking of toasts, that when a sentiment or toast would be demanded of him, it was his wont to lift his glass and pledge the company in this guise: "Here, my friends, is your very good health, and that is most consumedly against me." If the good old doctor had survived until the days when sanitary science was discovered, he would have been found acting in like manner as he phrased his toasts—at odds with his material interests.—*Gaillard's Medical Journal.*

Carburetted Hydrogen in Uterine Cancer.—Carburetted hydrogen mixed with olive or almond oil in equal proportions, is recommended by Dr. Drzewiecki, of Warsaw, in advanced cases of uterine carcinoma. Cotton-wool, saturated with the mixture, is applied to the ulcerated parts, after the vagina has been disinfected by means of a solution of permanganate of potassium or chlorinated water. This plan may be used when all other means have failed; it diminishes pain, and prevents the fetid emanations so distressing to the patient and all about her.—*British Medical Journal.*

Regarding the infant operation of ovariotomy, Professor Charles D. Meigs once said: "I detest all abdominal surgery. I am free to say that I look upon all operations for the extirpation of the diseased ovary as not to be justified by the most fortunate issue in any ratio whatever of the cases." "Dr. Atlee's coolness in cutting open a woman's belly does not, I think, entitle him to judge more clearly than I as to the morals of such surgery. . . . Dr. Atlee likes ovarian operations; on the contrary, I detest them, and should be glad to see them prevented by statute."

A Curious Account of Artificial Fecundation.—Another attempt to put it on a business basis in Paris is given by a correspondent of *The Medical Press.* Eight years ago a married couple in Bordeaux, despairing of having a family, consulted a Doctor Lajatre, who, by circulars spread about the country, pretended to render sterile marriages fruitful by a special operation. The doctor performed the operation, but no result followed, and his clients refused to pay him the fee demanded—£60. He thereupon summoned them before the magistrate, but this worthy representative of the law, after listening to the explanations of the doctor, which, by the way, were very minute, all the details of the operation being entered into, not only dismissed the case, but fined the plaintiff for revealing professional secrets. Further, the magistrate gave it as his opinion that artificial fecundation was repugnant to the laws of nature and a positive social danger, and that such procedures should not be put into practice. This verdict was taken up by the Society of Legal Medicine, as it is called, in France, and the president (M. Brouardel) said that the operation might be performed where, after other means had failed, no reasons were found in the man or the woman to account for sterility. Encouraged by this declaration, M. Lajatre came up to Paris, where he advertised in the daily papers his method of procuring families. It will be remembered that the Paris Faculty refused to accept a thesis on this subject presented by a student called Gérard. Last year a sort of company was got up in the capital, sending broadcast pamphlets entitled *Do Vitam*. A large apartment was hired in the Chaussée d'Antin, a doctor was engaged to do the operation, and for a time all went on well. Disappointed husbands and wives came in numbers, but some disagreement took place between the parties interested, and the whole matter has now been placed in the hands of the lawyers, from which it is not likely ever to come out.

Heredity and Temperament as Factors in Longevity.—Dr. B. W. Richardson states that if the ages at death, from natural causes, were obtainable of the parental lives of a man or woman through three generations, the average of their ages—the sum total of them divided by six—might be accepted as the commercial value of the last life. To this rule there were some variations, to the effect that, taking the age of sixty as a medium point, the value of the last life was less under that point, greater above it. Dr. Richardson also thinks that the bilious and sanguine temperaments are the best for long life, the nervous and the lymphatic the worst.

The Willard Parker Hospital.—The report of the Willard Parker Hospital, for the quarter ending July 1, 1888, shows a total of one hundred and seventy-eight cases treated, of which eighty-nine were of scarlet fever with a mortality of 19.1 per cent., and eighty-nine of diphtheria with a mortality of 20.22 per cent.; 82.35 per cent. of the deaths from scarlet fever occurred in children under five years of age, of which 42.9 per cent. were complicated with diphtheria. As compared with the corresponding quarter for 1887, there was an increase in the number of cases admitted of forty-eight of scarlet fever and forty-six of diphtheria, a total increase of ninety-four. Also, as compared with the first quarter of this year, an increase of twenty-one cases of scarlet fever and twenty of diphtheria, a total increase of forty-one. The admissions for the past quarter (of scarlet fever and diphtheria) show an increase over any previous quarter since the opening of the hospital, and only nine less than for the entire year 1886.

Hypertrophy of the Tonsils.—A Russian physician, Dr. Uspenski, has examined the pupils of a school in Moscow and found more than fifty of them suffering from enlarged tonsils. Of these the greater number were in poor health, three-quarters of them were more or less deaf, and one-third were myopic. Most of them suffered at the same time from a dry rhinitis and from granular or atrophic pharyngitis. Furthermore, all were backward in their studies, and were evidently intellectually inferior to their schoolmates.—*Revue Internationale des Sciences Médicales.*

Potassium Permanganate in Burns and Frostbites.—Dr. Zyboff has had great satisfaction from the use of permanganate of potassium in the treatment of burns and congelations. He keeps the parts constantly wet with a solution of from three-fourths to two grains of the permanganate to an ounce of water. If the integument is broken he employs a weaker solution, one-half grain or less to the ounce.

Sudden Death from Washing Out the Stomach.—Dr. Marten reports in *The Lancet* the case of a man, aged forty-eight years, suffering from dilatation of the stomach, caused by pyloric stenosis. Lavage of the stomach was practised, and the man had an attack of syncope immediately following, and died about six hours later. At the autopsy nothing was found except the stenosis of the pylorus and dilatation of the stomach.

Sesquichloride of Iron in Cavernous Angioma.—Dr. Studentski reports, in the *Chirurgicheski Vestnik* for April, 1888, a case of cavernous angioma, involving the entire thickness of the cheek and a part of the tonsil and palatine vault, cured by injections of a ten per cent. solution of sesquichloride of iron. One drop of the solution was injected every six days.

Recurrent Dental Abscess.—Dr. Kums reported at a meeting of the Société Médicale d'Anvers (*Annales et Bulletin*, April, 1888) the case of a lady suffering from an alveolar abscess, which presented periodical exacerbations occurring every afternoon at about four o'clock. The patient lived in a malarious district, and, suspecting a malarial cause for the periodicity, the author prescribed quinine, with the result of obtaining a perfect cure.

Meco-narceine is the name proposed by Laborde for a mixture of some of the alkaloids of opium remaining after the extraction of morphine and codeine, the chief of which is narceine. It is said to cause a profound and tranquil sleep, from which the patient awakes without any of the disagreeable after-effects experienced from a narcotic dose of morphine.

A Supposed Illegal Practitioner.—A man was arrested in Paris on the charge of practising medicine without the proper qualifications, but proved his innocence by exhibiting his diploma. On being asked why he pretended to be practising illegally, he said that he had tried to gain a practice after his graduation but failed. He then went into business, but by accident was called to give medical assistance several times to some of his neighbors, who were ignorant of the fact that he was a doctor. They paid him well, and sent other patients to him. He found that it paid to pretend to be a quack, for in the course of ten years he had made a fortune.—*La Pratique Médicale.*

Aphasia following Typhoid Fever.—Dr. Louis Arboleya reports, in *El Sentido Católico en las Ciencias Médicas*, June 1, 1888, the case of a boy, six years of age, who was suffering from typhoid fever. From the beginning of the disease the boy was dumb, and remained so at the time of the report, when he was already far advanced in convalescence. The hearing was unaffected.

Anæmic Sore Throat.—Dr. R. Scott Skirving calls attention, in the *Australasian Medical Gazette* for May, 1888, to a form of relaxed sore throat which he has found associated with anæmia. The subjective sensations are more pronounced than the objective alterations would seem to account for. There is a gradually increasing weakness in speaking, with some pain and stiffness in the throat, and lastly, considerable pain on deglutition, speaking, or singing. The mucous membrane is pale, with patches of rather deep congestion scattered here and there, for the most part behind the tonsils. Occasionally small submucoid hemorrhages are seen. The uvula is long, and œdematous at its point. There is a deficiency of moisture in the throat. The cough, which is a prominent feature, is dry and paroxysmal. The treatment consists mainly in the exhibition of remedies for the anæmia, chlorate of potash or rhatany lozenges being employed for local medication. The voice is apt to remain weak for some time after the anæmia is cured.

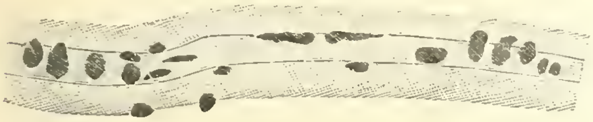
OBSERVATIONS ON INFLAMMATORY AND CERTAIN OTHER CHANGES IN THE MINUTE VESSELS OF THE PIA MATER.

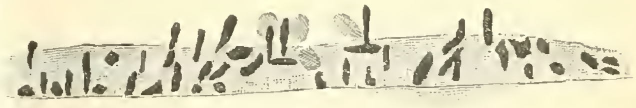
BY C. HANDFIELD JONES, M.B. CANTAB., F.R.S.,

LONDON, ENGLAND.

THE first change to be noted is that the extima, the quasi-homogeneous membrane which, in the normal state, lies evenly along the outer side of the corpuscular—the muscular—layer, is raised up to a less or greater degree and extent by a clear fluid. That it is detached and elevated is manifest, and also that the space included by this elevation is clear and transparent, so that it seems a matter of necessary inference that the effusion of a fluid—liquor sanguinis—is the cause of the change. Though it occurs early, it is by no means a necessary event, and when present it may be very partial. The elevated membrane is thrown into irregular prominences, much like the teeth of a saw, so that the margins of the vessel have a serrated aspect. In the intervals of the serrations the extima remains adherent to the corpuscular layer, and in some instances forms capsules, either full of clear fluid, or enclosing also one or two corpuscles. When the membrane is more extensively detached the enclosed space is, of course, larger, and may contain many corpuscles, mingled with varying amounts of granular matter. From this condition it is only a question of degree to that in which the whole surface of the arteriole is covered with a layer of corpuscles—the familiar periarteritis. Whether this term is correct seems to me questionable, as it is hard to conceive of inflammation restricted to the outer part of so thin a wall as that of an arteriole. That the so-called lymph-sheath now described is a normal arrangement seems to me impossible. The shape of the corpuscles varies; most of them are round or oval, but not a few are elongated, and closely resemble the endothelial nuclei, or those of the muscular layer. In the precapillary and capillary vessels fusiform corpuscles (endothelial) are often seen lying along the inner surface of the wall, in the "Randstellung" of the Germans, and as similar ones not infrequently lie just external to the wall, there can be no doubt, even apart from Cohnheim's experiment, that they actually traverse it. The great majority of the escaping corpuscles are of leucocyte character, and most of these are, no doubt, derived from the blood; but many also appear to proceed from the corpuscular layer, or its representative in the precapillary and capillary vessels. In this situation the transversely elongated nuclei of the muscular bands are replaced by round or oval corpuscles, adherent to the outer surface of the intima, which probably proliferate and separate. I must, however, mention here that in the arterioles of the tomentum—the deep surface of the pia—in meningitis the extima is well preserved, and forms, blended more or less completely with the intima, the whole arterial tube, enclosing the multitudinous corpuscles, endothelial, muscular, and leucocytoid. In such vessels there is no trace of muscular bands, though their enlarged nuclei are evident enough. Indications of multiplication by subdivision are frequent in all the various corpuscles. The endothelial particles are apt to become shorter and thicker, and so approximate, as also do the muscular nuclei, to the condition of oval leucocytes. In fact, it seems a character of the inflammatory "nisus," that it effaces all special features of cell-structure, and reduces them all to one common embryonal level. The endothelial nuclei pretty frequently are aggregated together in largish groups, occupying more or less of the vascular channels. The margins of the arterioles often present a row of corpuscles, some of them transversely elongated, the majority spherical. I am quite aware that the latter are held by many good observers to be only ordinary muscle-nuclei, which appear round in consequence of their marginal position causing them to bend round the edge. When this is the case, however, careful focussing detects the under-part of the bent corpuscle. The round corpuscles often project from the margin of the wall, and are evidently on the point of being detached. Occasionally elongated corpuscles are seen projecting at right angles from the wall. These are mostly muscle-nuclei.

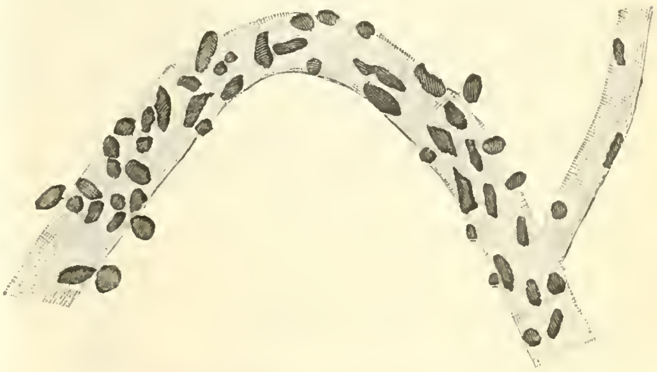


A. Lewington, No. 1.—Capillary, $^{1}/_{3800}$ inch diameter, containing corpuscles, several of which are escaping. It is surrounded with a feebly tinged subgranulous layer of the same thickness on each side as the vessel. Case of chronic meningitis. The insheathing layer is probably a chronic exudation.

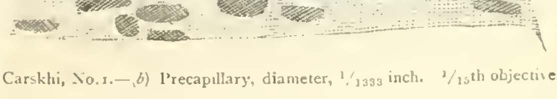


Charles Obern, No. 9.—Arteriole from pia, diameter, $^{1}/_{1250}$ inch. On left side of vessel, the wall about the mid-third is indistinct, and seven or eight corpuscles (muscle-nuclei) are escaping, together with four large colorless granular globules. On the right, at upper part, there is an imperfect lymphatic sheath.

Charles Obern.—(*a*) Large capillary, $^{1}/_{2500}$ inch, a single round corpuscle half escaped. (*b*) Similar capillary, $^{1}/_{3333}$ inch. The lowest corpuscle is pale and filmy.

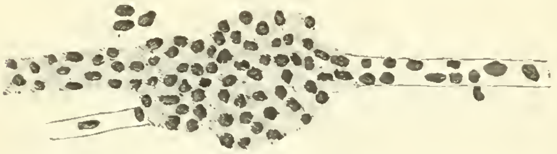


Carskhi, No. 1.—(*a*) $^{1}/_{1000}$ inch diameter. $^{1}/_{8}$th objective.

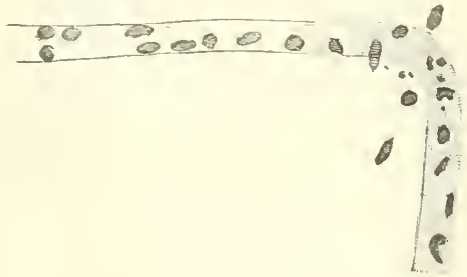


Carskhi, No. 1.—(*b*) Precapillary, diameter, $^{1}/_{1333}$ inch. $^{1}/_{15}$th objective.

Much red-stained granulous matter is frequently contained in the arterioles, along with corpuscles, and represents the débris of red globules which have been destroyed in making the preparation. Endothelial particles are sometimes mingled with this granulous matter, which demonstrates their position inside the tube of the intima. Loss of corpuscles sometimes goes on to such an extent that the walls of an artery $\frac{1}{300}$ inch diameter is reduced to the intima. blended perhaps with the extima and with an extremely scanty layer of fibrous tissue. A similar wasting is met with occasionally in the smaller vessels. To this change the term denudation may be applied. Corpusculation, on the contrary, denotes the opposite state, when a vessel is crowded with enlarged corpuscles heaped together more or less confusedly. Both these changes, though met with in meningitis, are by no means confined to it. In parts where the inflammatory process is more advanced, the surface of the minute vessels is covered with oval or elongate corpuscles protruding from the altered wall. The latter has lost more or less completely its normal structure, and appears as a strip of granular membrane where it can be discerned amid the overlying cells. In many instances the vessels, with their corpuscular coating, appear as solid cylinders, branching here and there into irregular processes, which often exhibit a plexiform arrangement by the union of lateral offsets with adjacent ones. These processes have some resemblance to granulations, consisting, as they do, of embryonal cell-particles. Escaping corpuscles sometimes form a linear series perpendicular to the axis of the vessel. Sometimes a small vessel runs through a large mass of corpuscles which seem to have proceeded from it. Smaller masses are seen now and then, either resting on the wall of a vessel, or dispersed through the rete of the pia. Appearances are not rare, suggestive of the eruption of corpuscles taking place in a focal manner, as if a vessel had given way at a particular spot, from which the particles diffuse themselves peripherally. If a specimen be carefully pencilled to remove most of the corpuscular formation, the change which has occurred in the vessels is very striking. The great majority have lost their normal structure, and are reduced to tubes of intima. The result of this must be to promote still more the occurrence of exudation from the blood. In some specimens the wall of the artery, though greatly changed, retains some of its corpuscles. No channel can be seen; the corpuscles lie, as it were, embedded in a tract of granulous matter.

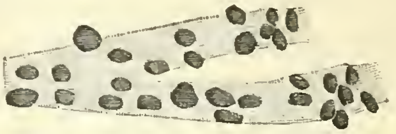


W. Sadler, No. 2.—(*a*) Small vessel running into a lobulated group of corpuscles mingled with reddish amorphous matter; a small capillary issues from upper part.



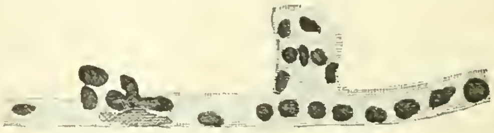
W. Sadler, No. 2.—(*b*) Precapillary with superficial corpuscles, one passing out. Two tiny corpuscles near bend, one, $^1/_{13500}$, the other, $^1/_{15000}$ inch. Vertical part of vessel of reddish-gray color.

A discrepancy may seem to exist between certain of the foregoing observations relative to the condition of the arterioles, they being found in many instances full of corpuscles, while in others they are empty, the corpuscles having escaped. The latter state I believe to be subsequent to the first. Two forces seem to be at work, one causing the multiplication and accumulation of corpuscles in the vessels, the other impelling them to wander out into the adjacent tissue. In the frog's web the first of these actions is seen to precede the second (*v.* M. Foster, p. 173). The same may be observed on a larger scale then by microscopy. I had a whitlow once which, after six days of active inflammation, continued very hot, painful, and swollen. Thinking that pus must have formed, I had it incised, but none escaped, and only four or five drops four days later. Here the emigrative tendency of the corpuscles remained in abeyance, though proliferation was probably active.

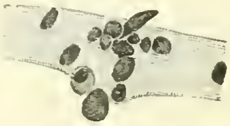


Charles Obern, No. 1.—(*b*) Tuberculous meningitis. Vessels with very faintly marked walls from pia.

The veins in meningitis present nothing remarkable, except that fibrinous coagula are more frequent than in the normal state. Elongate—probably endothelial—corpuscles are also frequently present in their contents, but this is not peculiar to inflammation.



F. Trippas, No. 5.—Capillary escaping corpuscles and bulging wall with corpuscles in cavity. $^1/_{15}$th objective.

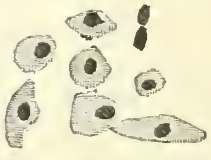


F. Trippas, No. 8.—(*a*) A large capillary containing corpuscles bulging the wall and escaping at both sides.

The capillaries in lower grades of the inflammatory process are normal; in more advanced they are either indistinct and filmy, or lost amid the abundant corpuscular formation.

The pia is often thickened, but not always in the same way. Sometimes the thickening is produced by numerous corpuscles fusing down into a layer spread over its surface. When this happens the corpuscles stain imperfectly with picro-carmine. Sometimes the thickening depends on the generation of filamentous webs, probably from the coagulation of liquor sanguinis, or, again, on the issuing of fibres, single or multiple, from corpuscles, and their coalescing in a plexus. This, of course, must not be confounded with the plexiform arrangement of the granulation processes above mentioned. The corpuscles of the pia in the normal state are very scanty, or may be so; but it is tolerably certain that slight deviations from absolute health may cause them to increase in number greatly.

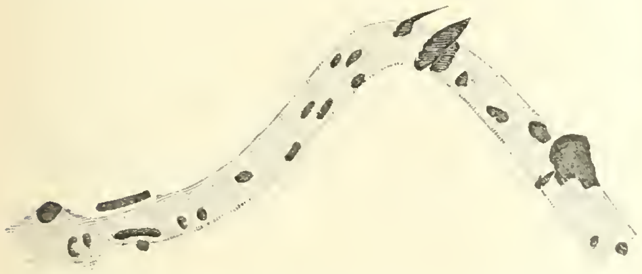
Capillary from same, $^1/_{6000}$ inch diameter. The vessel is slightly but distinctly bulged by the upper corpuscle. The lower one fills the lumen exactly. Its length is $^1/_{1430}$ inch.



From same.—Celloid corpuscles, and two probably produced by fission.

Nay, it is not to be denied that this may occur during the last few hours of life, or even after death. In the pia mater of a (presumably) healthy sheep I found, to my great surprise, the vessels throwing off corpuscles most copiously and extensively, and the tissue of the pia largely occupied by them, especially in the vicinity of certain (radiating) vessels. The condition closely resembled that of inflammation, but assuredly was not. In the next sheep I examined things were widely different. This result can only be explained by supposing, which is not unlikely, that the amœbic faculty varies a good deal in different individuals, in some being much more active than in others. It proves also that not all outwandering of corpuscles from the vessels is to be regarded as indicative of inflammation, even of a low grade. It does not, however, as I think, affect materially the value of the anatomical research I have made as to the changes occurring in meningitis in the human subject. But of this I must leave others to judge.

The main features of the inflammatory process now described are: (1) The excessive formation of indifferent cells; (2) the degradation of the special structure of the arterioles; (3) the amœboid wandering of the corpuscles; (4) the thickening of the pia by the fusing down of corpuscles and the development of plexiform filaments; (5) the presence of endothelial accumulations in some of the arteries. Inflammation is evidently in its essence degenerative, and depends for its existence on detriment of the higher power—whatever we term it—which originally framed organized structure, and in health maintains it. When this fails the lower powers of indifferent cell-growth and of amœbism are let loose and run riot. A muscular band has a special structure, a function, and a place; an indifferent cell has none.

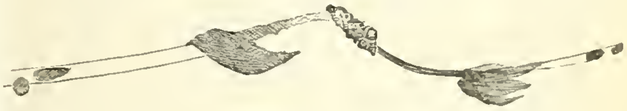


Walter Sadler, No. 15.—(*a*) Arteriole, $^{1}/_{1800}$ inch. Wall degenerate, appearing as a gelatinous film. Single corpuscles here and there, and two large corpuscular masses. It lies between centre of specimen and lower edge, close to a vegetable hair, and to micr. left of a blue mass.

Between passive congestion on the one hand, and active inflammation on the other, there intervenes a long series of morbid conditions approximating, more or less, to one or other type. The essential feature of the first is remora of the blood-current, and stagnation, with more or less escape of red corpuscles. The characteristic of the second is active growth and outwandering of leucocytes or indifferent corpuscles. In both the retentive faculty of the minute vessels is impaired, but much more gravely in the latter, where structural lesion often exists. Mitral stenosis, with its occasional hemorrhage, may be named as an example of the one; simple pneumonia, with its massive exudation, of the other.

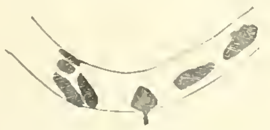
Endothelial Changes.—In some individuals whose arterioles appear normal, the endothelium is very evident, far more than is the case in most subjects, where it has to be demonstrated by the action of silver nitrate. It is seen after picro-carmine staining as a delicate layer or band, stretching along the middle third or thereabout of the channel and following its subdivisions. Occasionally, for a short distance, it lies *in situ*, applied to the free surface of the intima at one or both sides, but for the most part it has evidently separated and shrunk away from the wall. It is composed of delicate elongated nuclei, lying rather far apart from each other, attached to very thin plates representing cell-formations. These are of fusiform shape, as figured in Stricker's work, and are well seen in flakes which are sometimes found hanging out of the broken end of an arteriole, having been drawn out from the other fragment. Such is a correct description of normal endothelium, but very often it differs widely; the nuclei being no longer attached to cell-plates, but resting alone on the inner surface of the intima. Here they often greatly increase in number, aggregate in larger or smaller groups, and obstruct to some extent the channel. The development of the nuclei and the plates seems to vary inversely, hyperplasia of the former coinciding with atrophy of the latter. This difference in the condition of the endothelium, so far as I know, has not been noticed previously. The hyperplasic nuclei are sometimes very evident in the small veins, but are not found in the right cavities of the heart.

Quasi-vitreous Change.—The small cerebral arterioles present occasionally an atrophic condition, of the nature of vitreous alteration. The muscular fibres appear as pale, unstained, non-nucleated, glassy bands which extend beyond the intima, surrounding it, and by their translucency amid the intervening substance, somewhat resembling vacuoles. In specimens steeped in picro-carmine it is remarkable how the affected vessels refuse the stain, which others take so freely. This depends in large measure on the absence of the nuclear corpuscles, which in the normal state become colored so readily. It is not always easy to distinguish this vitreous change from that in which remnants of the lymphatic sheath form capsules around the parietal corpuscles. I am not clear that this so-called vitreous change is a degeneration; it seems to be rather atrophy of the nuclei than of the muscle-substance itself. Perhaps it is not morbid. It has some resemblance to amyloid change, but is essentially different.



Walter Sadler, No. 15.—(*b*) Capillary with extravasations of corpuscles and granulous matter.

Atrophic Change.—In two instances I have observed remarkable wasting of the corpuscles of the capillaries and precapillaries. One of these occurred in a male, aged fifty-six, dead of morb. br., with embolism of the right lenticulo-striate artery, and consequent softening of the hemisphere. A lamel of pia mater from his brain contrasted extremely with one from a case of typhoid fever with albuminuria and delirium. The latter was crowded with plump corpuscles free or adherent to the vessels, the former contained only scanty and shrunken corpuscles. The other instance was that of a female, aged twenty-six, dying with a sarcoma of walnut size springing from the sella turcica, and probably impeding the blood-flow through the large divisions of the carotids. The corpuscles of the capillaries and precapillaries in her brain were scanty and wasted, and contrasted strongly with those of a child, aged three, examined at the same time, who died of catarrhal pneumonia attended with violent and persistent screaming. The fibrous rete of the pia mater varies much as to its amount of corpuscles. Sometimes this is scanty, and its individual corpuscles are small and mingled with much granular matter; sometimes, especially in states of active hyperæmia, the corpuscles are multitudinous. Even in the same brain, great difference in the condition of the pia in this respect may exist in different places.



Charles Obern.—Tubercular meningitis. Precapillary from pia of cortex, diameter, $^{1}/_{2000}$ inch. (*c*) A corpuscle is shown protruding a pointed process through the wall.

Atrophic states are not rarely met with among arterioles in which all trace of normal structure has wellnigh disappeared, and the vessel is reduced to a mere strip of fibroid and granular stuff without any apparent channel. I am much disposed to regard these conditions as late results of corpuscular hyperplasia, such as occurs in the so-called periarteritis, the process terminating in the destruction of the artery. Long after I had observed the change, an eminent pathologist suggested to me the inquiry, whether arterioles might not have a term of life ending in decay ("Path. Trans., 1883").

Atheroma.—The atheromatous change appears to me, after numerous careful examinations, to consist essentially in deposition of oil on the surface of the intima, or at a little depth below it. The oil-drops vary greatly in size from the most minute to the largest, say $\frac{1}{500}$ inch diameter, and are unmingled with any other formed substance, except occasionally with granules very numerous and much resembling micrococci. The atheromatous matter, as it accumulates, encroaches on, and causes wasting of the wall of the arteriole, which in some places yields and, gives rise to aneurismal bulging of well-marked character. The nature of the deposit is clearly shown by the blackening effect of osmic acid. The patches are often singularly local, a trunk with numerous primary and secondary ramifications remaining healthy, except in a few spots. This opposes the idea of the smaller patches being embolically derived from larger and more centric (*vide* "Path. Trans., 1883").

In what I have termed the *diffuse* form of atheroma, the walls of the minute arterioles are lined with a reddish-brown semi-opaque matter, rendered translucent by liquor potassæ, but darkened by osmic acid. Oil-droplets, in varying amount, are seen in it. The change is frequently met with, but its nature is uncertain.

Coagula.—In examining small cerebral vessels it is not rare to find colorless coagula in their channel. These are often microscopic, but often also are distinctly visible to the naked eye, especially when stained. They consist of amorphous basis-substance, with the usual fibrils and leucocytes, and contain besides, in most instances if not in all, extremely numerous small granules, $\frac{1}{30000}$ to $\frac{1}{10000}$ inch in diameter. The larger sometimes appear as minute vesicles having a wall and pale contents; the smaller are more like solid particles, and have sometimes an angular outline, or are more or less elongated. The granules are more constant in the coagula than the leucocytes. Sometimes in a specimen a tract is occupied with granules alone, while another adjacent is full of corpuscles, or of corpuscles mingled with granules. The latter stain strongly with methylene blue or gentian violet, certainly more deeply than the fibrils between which they lie. They are not dissolved by liq. potassæ. Vegetations on the cardiac valves are sometimes very largely made up of these granules. sometimes contain few, if any. They are found also in the sputa of lung inflammations in great abundance.

In a case of pneumonia, on the tenth day, the sputum contained multitudes of granules, but very few pus-corpuscles. Many of the granules, especially the elongated ones, were seen moving actively. This circumstance, and their considerable variation in size. due probably to growth, indicates their possession of vitality, at least during the earlier period of their existence. To this may be added that the larger ones bear a very close resemblance to micrococci and take blue stains freely. In a case of ulcerative endocarditis, with quasi-abscesses in the mitral valve, the contents of these foci consisted very largely of similar granules, varying in diameter from $\frac{1}{20000}$ to $\frac{1}{5000}$ inch, together with bacilli. The septic character of the disease, and the presence of bacilli among the granules, marks the condition as one in which micro-organisms of various kinds would be likely to appear, while the presence of inflammatory products would naturally be expected. What difference exists between a pus-corpuscle, a bacillus, and a febrine granule, *quâ* vitality, is hard to state.

THE FREQUENT DEPENDENCE OF PERSISTENT AND SO-CALLED CONGESTIVE HEADACHES UPON ABNORMAL CONDITIONS OF THE NASAL PASSAGES.[1]

By JOHN O. ROE, M.D.,

ROCHESTER, N. Y.

There is perhaps no single affection that causes so large an amount of human suffering, and which is regarded so lightly, as that known by the generic term, headache.

There is also no affection that has so many different types, nor one which is caused by such a great variety of bodily conditions. It not only attends nervous affections, but is a frequent complication of nearly every other form of disease.

A headache is in every instance a warning of some disease or derangement that should be sought out and corrected. Dr. Day very truly says: "The subject of headache is of manifest importance, because it claims so many sufferers and is surrounded by so many difficulties —the pathology is obscure, the diagnosis perplexing, the remedies uncertain. Headache is a disorder of the utmost frequency, and yet there is none which more taxes the experience and scientific knowledge of the physician, or requires closer observation in elucidating its nature and removing its obscurity.[2]

The connection between abnormal conditions of the nasal passages and certain forms of headache was recognized a long time before we had any definite knowledge concerning diseases of the nose. These headaches were, however, only those observed to be associated with, or caused by, an engorged condition of the nasal passages, usually that attending a cold in the head, and were therefore termed "catarrhal headaches."

Headaches caused by chronic abnormal conditions of the nasal passages, in which the nasal derangement played a less conspicuous part, were sometimes attributed to other causes, and the nasal disease was entirely overlooked or unsuspected. In case of entire failure to detect a cause, the headache was often termed "nervous" or "congestive," or by that most comforting of terms, "idiopathic."

The physical relations of the nose to the other portions of the human system are very important; for in diseases of this organ not only are the well-known offices which it performs interfered with, but derangements are produced in other organs and parts. Such derangements may be the effect not simply of cutting off nasal respiration, but of the irritation that is reflected from the nose to other parts through its abundant nervous connections.

An impetus was given to the study of nasal neuroses when it was shown that nearly all the phenomena attending hay fever were reflected irritations from the nose; and also that many other neuroses, such as megrim, facial spasm, choreic symptoms, epileptiform seizure, sneezing, cough, laryngeal spasm and asthma, were frequently excited by disease in the nasal chambers.

With this array of symptomatic effects of nasal irritation, together with the proximity of the nasal chambers, and their communicating cavities, to the brain. we would naturally expect to find morbid impulses quite as often reflected to the head as to any other region.

For the purpose of illustrating the clinical character of headaches of nasal origin, I have selected from the many instances that have come to my observation the following cases:

Mr. A. K——, fifty years of age, had been subject to persistent headaches for fourteen years. At first the headache was slight. He would awaken with a headache in the morning, which would pass away during the early part of the forenoon, after exercising in the open air. This symptom steadily increased in severity and would continue longer during the day, until for two years previous to the time I first saw him, his headache was persistent and continuous during the entire twenty-four hours. The pain was confined to the upper portion of the frontal region. There was no pain over the region of the frontal sinuses. The pain was a dull ache, like a sensation of pressure, with a feeling of fulness throughout the head. When I saw him, the pain had become so severe as to be almost unbearable. His ideas were confused and his memory had begun to fail him, so that he was apprehensive of softening of the brain or some other severe disease in his head. A short time before his headache commenced he began to be troubled with what is termed a "catarrhal" difficulty, with more or less stoppage of the nostrils—particularly the left one—and also with considerable discharge. On lying down his nostrils became stopped and he was obliged to breathe through his mouth during sleep. His throat would become parched and dry, and there would be left a bad taste in his mouth in the morning. His headaches were considered to be a form of congestive headache, due to what is commonly termed "biliousness." He was treated by a variety of different physicians—regulars, irregulars, and defectives—with no permanent benefit. A great deal of quinine was given him by those supposing it to be of malarial origin. The only medicines that seemed to give him any relief whatever were active cathartics, which seemed to confirm the congestive and bilious theory. Accordingly, for the two years previous to the time I saw him he took a cathartic every day, such as pills of some sort, salts, senna, castor-oil, rhubarb, cream of tartar, etc. A Turkish bath would also give him complete relief during the time that he was in the bath.

---

[1] Read before the last Session of the Medical Society of the State of New York.

[2] Headaches: Their Nature, Causes, and Treatment. Am. Ed., 1883, p. 11.

On examination of the nasal passages I found a bony ridge projecting from the left side of the septum and pressing firmly into the left middle turbinated body. There was also some hypertrophy of both the inferior and middle turbinated bodies on that side. On the right side there was some general thickening of the mucous membrane, but the nostril was comparatively free.

The bony ridge I removed with a nasal saw, and applied the galvanic cautery to the turbinated hypertrophy. The result was complete and almost immediate relief from the headaches. For some time his whole scalp had been so sensitive that he could not endure the slightest pressure, but this sensitiveness of the scalp disappeared almost entirely with the headache. He is, however, still sensitive to draughts of cold air, but by keeping his head warm with a skull-cap or other closely fitting cap, he is exempt from every vestige of headache. Since he ceased treatment two years ago he has taken no medicine whatever, has enjoyed perfect health, and now says he feels better than he has at any time in fifteen years.

Mr. E. R——, aged twenty-seven, cigar-maker by trade. For a year and a half he had experienced an obstruction in the nose which seemed to follow a severe cold in the head. This was followed by more or less ringing in the ears, profuse discharge from the nose, and soon after by a severe headache or pain confined to the occipital region on that side. He also had more or less intermittent pain in the left side of the chest. This condition continued, and the pain grew steadily worse until he had to give up all work and became seriously alarmed as to his condition. He was subject to frequent colds in the head, his nostrils were most of the time stopped, and he was obliged to breathe through his mouth. He was also subject to frequent attacks of sore throat.

On examining his condition a bony ridge was found projecting from the left side of the septum, prodding into the lower turbinated body on that side, very similar to the case just described.

There was also marked hypertrophy of the middle turbinated bone, which pressed firmly against the septum above this region. On the left side there was marked inferior turbinated hypertrophy, which almost completely occluded the nostril. On removal of these abnormal conditions the pain disappeared, and there has been no return of it since. The general condition, which had become much reduced, at once rapidly improved. He went back to his work and has had no trouble since.

Mrs. J. K——, aged thirty-one, had had nasal catarrh and obstructed nostrils for eight years, and during each summer hay fever very severely. Four years previous to the time when I saw her, she began to have frequent and severe headaches affecting the whole head, but more intense over the supraorbital and frontal regions. She had a profuse discharge from the nose. She also had tinnitus aurium, but her hearing was not impaired. She became unable to use her eyes to read or sew, on account of a headache which was immediately brought on. In general health she was weak and anæmic.

On examination of her nasal passage I found both inferior and middle turbinated hypertrophy, on both sides, obstructing the nostrils anteriorly and posteriorly. Most of this projecting was removed with a snare, and the remainder with the galvanic cautery. After some subsequent treatment the nasal stenosis was completely removed and nasal respiration became entirely free. The headaches disappeared, as did also the sensitive condition of the eyes, so that she could read and sew, and use her eyes without the slightest discomfort or headache. Her general health improved. She began to gain in flesh and strength, and during the five years which have since elapsed she has remained entirely well, with no return of the headache or the hay fever.

Miss K. C——, aged twenty-six. For two years she had experienced a great deal of obstruction in the nostrils, with a sensation of pressure about the bridge of the nose, sensitiveness of the eyes and lachrymation, pain about the head in the temporal and frontal regions, but particularly back of the neck. She also had a profuse discharge from the nose, and frequent hoarseness.

On examination the middle and superior turbinated bones on both sides were found greatly enlarged and pressing firmly against the septum. There was very little other trouble found in the nostrils. The inferior turbinated bodies were not hypertrophied. Pressure over the inner wall of the orbit on either side would greatly increase the pain on that side of the head. The treatment consisted in removing the hypertrophied portions of the middle turbinated bodies which pressed against the septum. The headaches were at once relieved, as was also the sensitive condition of the eyes and the lachrymation.

Mr. L. H——, aged fifty. He had experienced trouble in the throat since he could remember. During the past four years he had had much obstruction of the nostrils, with profuse discharge, and also a severe but dull pain and a sensation of pressure about the bridge of the nose, with a dull headache extending through the frontal and temporal regions.

On examination of his nose, on both sides, there was found inferior posterior turbinated hypertrophy. On the left side, the middle turbinated body was found enlarged and pressing against the septum, while on the right side of the septum, along the superior border, there was a thick ridge of tissue of a doughy consistency, which was pressing against the superior turbinated body on that side. The removal of these abnormal conditions in the nose resulted in complete relief from the headache and of the noticeable symptoms of the nasal difficulty.

Mrs. J. R——, aged forty-three. Throat sensitive, and subject to frequent colds in the head for several years. During the past three years she had been subject to headaches, slight at first, but gradually increasing in severity. They were confined mainly to the frontal regions, but at times severe pains, which she considered neuralgic, would extend throughout the whole region of the scalp. She had also more or less stoppage of the nose, and was obliged to sleep with her mouth open. In the morning her mouth would be dry and parched. She also suffered from a great deal of irritation about the throat and was frequently hoarse.

On examination of the nose there was found, on the right side of the septum, an exostosis projecting against the middle and superior turbinated bodies, which were very sensitive to the slightest touch of the probe. There was also some inferior posterior turbinated hypertrophy on both sides. There was a pad of hypertrophy along the upper border of the septum, on the left side, pressing against the middle turbinated bone. The turbinated hypertrophies were removed, the hypertrophies of the septum, and the bony projection. With the necessary subsequent treatment the nasal difficulty was entirely relieved and the headaches wholly disappeared.

Mrs. D. G——, aged forty-two. For several years she has had more or less obstruction of, and discharge from, the nostrils, attended with very severe headaches. She was subject to frequent attacks of cold in the head, which would at once bring on a headache. These attacks were considered to be of a congestive nature. The headaches at first were slight, but afterward they became much more severe and persistent. Sometimes a severe attack would be attended with nausea and vomiting. Occasionally these attacks would supervene during some change in the weather, and without the evidence of a cold. She was very sensitive to the inhalation of dust or damp air, which would bring on a headache. Her general health was much impaired. Examination of her nose revealed a firm hypertrophy or enlargement of the middle turbinated body, which pressed against the septum. There was also some inferior posterior turbinated hypertrophy on both sides, and a pad of thick, soft tissue on the right side of the septum, near the upper portion, pressing against the middle turbinated body on that side. These abnormal conditions of the nose were removed. The headaches and attacks of nausea speedily disappeared, and, with the administration of tonics of bark and iron, she soon became restored to a condition of vigorous health.

Etiology.—Headaches that have their exciting cause in the nose are reflex in character. This is a self-evident fact, for the reason that the manifestation of pain is at a point more or less remote from its exciting cause in the nose.

The exceptions to this statement are where the pain occurring directly over the frontal sinuses is due to the disease of these sinuses; or to the accumulation of secretions or of mucous discharges in these sinuses caused by obstructive swelling at the opening of these sinuses, or to hypertrophic rhinitis; or to the direct extension of disease from the nasal cavity to the meninges and brain. Such extension, however, very rarely occurs.

It may occur, nevertheless, when the cribriform plate and the upper portion of the lateral masses of the ethmoid bone are quite extensively diseased and undergoing necrosis, or it may take place through the communication of the lymphatics of the nasal mucous membrane with the supraorbital and subarachnoid spaces. It has been demonstrated that by injecting fluids into the latter spaces with sufficient force, such fluids can be made to pass through the lymphatic canals to the surface of the mucous membrane. Therefore, if these nasal lymphatics become obstructed, it is not impossible that more or less pressure might be made on the cerebro-spinal fluid.

The exciting cause of nasal headache is an irritation of the terminal nerve-filaments in the nasal chambers, which excites an undue activity in the communicating ganglion, and from which an irritation is reflected to the terminal filaments of other communicating nerves. This undue activity of the sympathetic ganglia also causes a dilatation of the smaller vessels and the capillaries, and a greatly increased vascularity of the part takes place, which, being associated with the head pain, is recognized as a congestive headache. Sometimes, when the irritation is great, the congestion will be intense. The vessels of the scalp will be full and bounding. There is often more or less hyperæsthesia of the scalp, with a sensation of heat at the spot where the pain is most intense, or a sensation as if a nail were driven into the scalp, a "clavus" which the patient will sometimes instinctively indicate by a gesture. It is in this manner that other well-recognized headaches, due to irritation reflected from distant parts and organs, are caused; as, for instance, those due to uterine irritation, and most commonly expressed by a vertex pain; those excited by derangements of the stomach, causing irritation of the gastric plexus of the sympathetic, and reflected to the frontal region; and those due to eye strain, and manifested by pain in the region of the orbit and temple.

In the latter case the irritation is caused by the effort of the ocular muscles to adjust themselves so as to overcome a defective accommodation, and as soon as the irritation is removed by ceasing to use the eye, or by the use of properly adjusted glasses, the consequent headache ceases. The frequent occurrence of the dependence of severe headaches on defective accommodation of the eye is shown by the number of reports of such cases that have been, during the past few years, scattered through our medical literature. Many cases of eye trouble due to disease in the nose are also reported.

In the nose, the irritation is occasioned by some abnormal condition which brings together parts that normally should be separate, and produces more or less pressure between them.

In no case of headache, either temporary or persistent, excited by nasal irritation, have I failed to find the irritation to be due to such pressure in some portion of the nasal chambers. I should except polypoid or other growths in the nose, which will produce pressure, and frequently severe headaches, but in such cases the parts are forcibly separated. This pressure may be constant or only during the period of temporary engorgement of the soft parts, which brings them forcibly together or against the septum. There may be an exostosis of a turbinated bone prodding the septum, or a firm hypertrophy of a turbinated body pressing against it; or the septum may be markedly deflected, or there may be a bony ridge or sharp spur projecting from it prodding a turbinated body.

When one wall of a nasal passage comes in contact with its opposite wall, sooner or later the resulting irritation causes a sensitiveness and thickening of the tissues of the latter side.

It is not uncommon that a sensation of fulness is felt at the base of the nose and about its bridge, associated with more or less head pain, due to an enlarged middle turbinated body wedged in tightly against the septum.

I have also not infrequently found a pad or oval mass of tissue located on the septum, near its upper border, opposite to and pressing against the middle or superior turbinated body. These are almost always very sensitive to irritation, and in persons subject to hay fever they are extremely so.

Character and direction of the pain.—The character of the pain varies from a dull, heavy ache, like that from undue pressure, to a sharp pain, like that characteristic of neuralgia. The pain also may be intermittent and more or less transient, recurring at frequent, and, it may be, regular intervals, or it may be persistent or nearly continuous.

In the latter case it is, as a rule, due to a constant pressure between parts that are found to be bony or composed of more or less firm tissue; while in cases of transient pains the pressure is between soft tissues, and on the subsidence of the engorgement the parts separate and the pain disappears. In other words, when there is constant pain there is a correspondingly constant pressure, and in temporary attacks of pain the pressure is correspondingly temporary.

Certain atmospheric conditions will excite headache. It is usually when there is a low temperature and low barometer, with the air surcharged with moisture—a condition that causes these diseased nasal tissues to become engorged and also distended by the absorption of water from the atmosphere.

Various conditions of the body have an influence on the nose and cause reflected headaches. Gastric and hepatic disturbances and a plethoric condition of the system will not only produce a fulness of the cerebral vessels by sympathetic irritation, but also a distention of the cavernous sinuses of the nose, thus producing intranasal pressure.

The connection between the nose and stomach is often experienced by those who indulge in wine dinners, and tax their stomachs beyond their normal capacity with *pâté de foie gras* and other like substances of difficult digestion; for it is rarely that they escape a cold in the head and a matutinal headache. Persons who have organic derangements in the nasal passages can rarely indulge to excess in eating, drinking, or nervous excitement without exciting a coryza and an associated headache.

It is to be noticed in those cases in which an engorged condition of the nasal passages is associated with a headache, that the pain is mainly located in the region where a pain is experienced by the same individual when suffering from what he considers a purely catarrhal headache. In the latter case the relation between cause and effect is recognized by the individual, but in the former instance the pain is attributed to some other cause.

The location of the pains in the head has no constant relation to the disease nor to its seat in the nose, and it has no such relation to the distribution of the nerves or blood-vessels. As I have pointed out in a previous paper,[1] an irritation reflected from the nose (or from any other part, as the case may be) is, like the electric current, reflected always in the direction of the least resistance. It may be reflected in one direction at one time, and in another at another time. Therefore, from the same region in the nose the pain may be reflected to the vertex, to the occiput, the parietal, temporal, or frontal region; or it may be spread out over the whole surface.

In some cases, as we would naturally expect, when the abnormal condition in the nose is confined to one side, we have a hemicrania on that side; but this is not always true, as shown by some of the cases cited.

Notwithstanding the fact that the location of the pain in the head bears no *constant* relation to the location of the disease in the nose, it is observed that from certain portions of the nasal chamber pain is *more often* reflected to certain regions of the head than to other regions. Thus from the inferior turbinated body and lower portion of the septum the pain is most often reflected to the lower and posterior portion of the temporal, parietal, and occipital bones.[2] The pain reflected from the region of the middle turbinated bone is commonly referred to the temple, sometimes invading the whole region from the nose to the parietal eminence, and extending to the vertex; while pain reflected from the region of the superior turbinated bone is commonly felt in the frontal and supraorbital region. Sometimes the pain will completely surround the eye, or be centred in the back of the eyeball.[3]

Diagnosis.—The dependence of persistent and so-called congestive headache upon abnormal conditions of the nasal passages is sufficiently frequent to call for a careful examination of the nasal passages in a large proportion of such cases. In fact, in all cases where there is not an unquestionable relation of cause and effect between some other local or general disease and the headache, the nasal passages should be interrogated, even in the absence of urgent or distinctive symptoms of nasal disease.

It is too frequently the case that a well-pronounced nasal trouble is looked upon as nothing more nor less than an ordinary "nasal catarrh;" while the headache that results from the disease in the nose is considered to be chronic neuralgia, as was the case with some of the patients whose cases I have reported, and the patient is teased for months, or years, until general debility, nervous prostration, or a neurosis is developed.

The necessity for an exhaustive study and careful examination of each particular organ that may, by any possibility, contain the exciting causes of any obscure neurotic affection, cannot be better illustrated than by the affection under consideration.

In case the headache is associated with pronounced nasal irritation, and there is an absence of any other pronounced cause, such as gastric disturbance, eye strain, uterine and renal disease, rheumatic and lithæmic affections, or the effects of drugs, such as cocaine, and sometimes quinine, we have presumptive evidence that the headache originates in the nose.

Further evidence we should seek for, by carefully examining the nasal passages. If we see evidence of one or more of the various diseased conditions in the nose, already described, that may be the cause of headache, we should carefully explore the part with a probe. Usually the slightest touch of the probe against the offending part will provoke the characteristic head-pain. This connection is more pronounced during the exacerbation of the pain than during the period when the nasal irritation is in a condition of comparative quiescence.

Dr. Harrison Allen[1] has called attention to the effect of pressure upon the inner wall of the orbit; the pain that is caused thereby being due to the pressure of the anterior end of the middle turbinated bone against the septum. This pain, he observes, is reflected on a line from this point to the temple, and sometimes to the parietal eminence; while pressure of the entire bone against the septum will give rise to vertex pain.

The treatment of headaches dependent on intranasal disease consists in the removal of the cause and the restoration of the nose to a normal condition. The conditions which we may have to deal with as possible causes of cephalic pain have been described under the head of etiology.

Dr. Glasgow,[2] of St. Louis, has called attention to the immediate relief given in the case of "congestive headaches" by the abstraction of blood from the cavernous sinuses of the nose.

He observed that, during a congestive headache, the cavernous bodies of the nose were always in a condition of intense hyperæmia, and that on the abstraction of blood from these bodies the hyperæmia disappeared and the headache subsided. The abstraction of blood was accomplished by simply puncturing the cavernous bodies with a needle, and the flow of blood was proportionate to the amount of engorgement—from a drachm to several ounces. This also illustrates very clearly the dependence of headache on intranasal pressure.

The prognosis in regard to the result of the treatment and the relief of the pain will depend entirely on the accuracy of the diagnosis and the care with which the indications are carried out; for, when the cause is gone the symptoms will disappear—*sublatâ causâ tollitur effectus.*

[1] Hay Fever: An analysis of forty-four cases treated by the writer, together with results of treatment, New York Medical Journal, 1887, vol. xlvi., p. 225.

[2] Pain may be reflected from this region in other directions. A little more than a year ago a gentleman, aged forty, consulted me in regard to a naso-pharyngeal affection that troubled him very much. He also complained of a continuous dull pain in the upper portion of the left side of his chest, which greatly annoyed him, lest it were due to some disease of the lung. I examined his chest, but could not find the slightest evidence of disease there. In his left nostril there was a bony ridge projecting from the left side of the septum, near its lower border, and pressing into the left inferior turbinated body. On the removal of this bony ridge in the treatment of his nasal disorder the pain in his chest entirely disappeared, and there has been no return of it since.

[3] Since this paper was read, a lady, aged fifty-five, was referred to me for treatment for a frequently recurring slight epistaxis from the left nostril, which I found to be caused by a small ulcer near the upper portion of the triangular cartilage. She also suffered from periodic headaches, occurring regularly every three weeks. The pain was confined to the right supraorbital region, surrounded the right eye, and extended in behind the eye. During the two weeks previous to the time I saw her, she had also had divergent strabismus of this eye. Examination of the right nostril showed a rounded pad of hypertrophied tissue on the right side of the septum, near the upper border, opposite the superior turbinated body. It completely filled the passage at that place and pressed against the superior turbinated body. Pressure with a probe against this spot was referred to the supraorbital region, while pressure against the superior turbinated bone caused a sharp pain in the back of the eyeball. On taking away this pad of hypertrophied tissue, pressure against the superior turbinated bone was removed, and there has been no headache or pain in the eyes since, and the strabismus has disappeared.

ELECTRICITY *vs.* LAPAROTOMY IN INFLAMMATORY AFFECTIONS OF THE UTERINE APPENDAGES.

By EGBERT H. GRANDIN, M.D.,

NEW YORK.

Notwithstanding the earnest protests which have emanated from more than one quarter against the dictum that laparotomy, followed by the removal of the appendages, offers the sole hope of cure in case of disease of these organs, this radical method is still advocated with as much zeal as a few years ago when the wave of laparotomy, starting from Birmingham, swept over this country with a force which boded ill to womankind and awakened alarm in the breasts of what I may term the conservative element in the profession. The aim of the average gynecologist became at once to rival, if possible, the wizard of Birmingham, and our journals began to teem with the records of *successfully removed* tubes and ovaries. The series has gone on lengthening, and to-day it is no uncommon matter to peruse the tabulated results of twenty-five, fifty, or one hundred and more laparotomies of a single operator. Iodine to the vaginal vault, the glycerine tampon—these agents of the past have been laid aside, and the knife has full sway. In skilful hands few of the patients die of the operation; many are restored to usefulness, minus their appendages; a small minority suffer as much as they did before running the risk of laparotomy.

Not so very long ago, when pretty much everything of an inflammatory nature around the uterus was termed cellulitis, the persistent tamponnade and counter-irritation of the vaginal vault, associated with the hot douche, unquestionably restored many a woman to health and to usefulness. Later, when the majority of these instances of cellulitis were recognized as cases of pelvic peritonitis, associated generally with tubal disease, the impression began to gain ground that the only means of curing these patients was to remove the tube or tubes whence, in the vast majority of cases, emanated the affection of the pelvic peritoneum. Such argumentation was scarcely in accord with strict logic, but the wish became the father of the thought. What was possible in case of cellulitis ceased to be in case of peritonitis, and the offending organs had to be removed. What is the use of these tubes and ovaries to the woman? became the dominant question. They are diseased, *ipso facto* the woman is sterile; by removal the woman is surely not altered for the worse. And so these appendages have been removed, and are daily being removed, and the record of successfully performed laparotomies is swelling, in utter oblivion of the fact that suffering is by no means always lessened, and that a not inconsiderable proportion of laparotomized women are to-day finishing where they should have begun—having iodine applied to the vault, the glycerine tampon inserted; or, better still, in the opinion of the writer, receiving the benefits of electricity rationally utilized, as a great palliative if not always a curative agent.

Such statements as the above are not strictly novel, but reiterated they must be until, in a certain class of instances of disease of the appendages, the knife yields, as it must, to electricity. In my own case this belief is founded on results personally obtained in cases where laparotomy has been advised by high authority, and in such instances I desire to maintain the superiority of electricity over laparotomy from a conservative stand-point, seeing that the agent is capable of as much good without risk and leaves the woman with unmutilated procreative organs, even though these organs may never furnish outward evidence of thorough function beyond that which is offered by menstruation.

The class of cases in which I would contend electricity will prove as serviceable, and frequently more so than laparotomy, and this, too, without subjecting the woman to the slightest risk, are those in which careful exploration, if necessary under anæsthesia, fails to suggest the presence of pyo-salpinx. Disease of this nature calls for speedy and radical action. The knife is here indicated, even as it is in any other region of the body where pus is predicated. A history of recurrent attacks of pelvic peritonitis should constitute the call for laparotomy, lest the next attack should eventuate in a general peritonitis fatal to the patient. Where, however, the careful bimanual exploration of the patient, the rational history, and the appearance do not suggest the likelihood of pyo-salpingitis, then the greatest palliation, if not entire cure, may be predicated from resort to electricity. The conditions termed catarrhal salpingitis, pachy-salpingitis, peri-salpingitis, peri-oöphoritis, I would include in the class which may properly be subjected to electricity rather than to the knife.

When I first began to systematically use electricity in my gynecological practice, I deemed it contraindicated in acute pelvic peritonitis—the term under which, for the sake of brevity, I would include the affections just referred to—and to be used with caution in subacute instances. With increased experience I have learned that the agent may not alone be resorted to with safety, but with benefit as well, where the condition is acute. By means of electricity the circulation is regulated, absorption is favored, and we effectively counter-irritate. The technique of the application I have so recently described that it is unnecessary here to do more than lay stress on certain of the cardinal principles. Notwithstanding the advocacy of Apostoli, Engelmann, and others, I am not convinced that it is at all essential to success to use currents of great intensity. Indeed, in certain instances, I am satisfied that I obtain greater benefit through resort to weak currents of considerable duration. The action of the current is thus more prolonged, and the effect more lasting. The non-active pole, and this will ordinarily be the negative pole, should cover as large a surface as possible, the abdomen being the preferable site for its application. As long as there exists tenderness on pressing the vaginal vault, or pain in imparting motion to the uterus, galvanism is indicated, the positive—the anæsthetic, alterative pole being placed within the vagina. When the symptoms have disappeared, faradization, first the primary current, and later the secondary, will be found most effectual in completing the cure in so far as this is possible. In the intervals between the séances, and these should be held every other day, at the outset, the uterus should be gently supported by a wool tampon—the organ should not be crowded up by a number of tampons packed as solidly as possible into the vagina, for thus as much harm is done to the ligaments, blood-vessels, and adjacent organs in an upward direction, as they suffer when, without the tampon, the uterus sags downward. Attention to these simple rules is strictly essential to success. Through resort to electricity the gynecologist may not gain such great renown as the operator who can boast of a long series of operations, and who can exhibit to colleagues and to patients the bottled specimens, emblems of his prowess, but he will have the satisfaction—no mean one—of knowing that he has relieved suffering without risking life, and he will find that a reputation for conservatism bears golden fruit in plenteous harvest.

109 East Fifty-fourth Street.

To Prevent the Condensation of Vapor on Lenses in the Throat.—Dr. Stocquart, in the *Paris Médical*, calls attention to an easy method for preventing the lenses of instruments from becoming dim while being used to examine cavities. It suffices to spread a drop of glycerine on the lens. This done, it can be introduced in the throat, for example, without becoming dim.—*London Medical Recorder.*

SOME REMARKS ON THE TREATMENT OF PLEURISY BY SALICYLATE OF SODA AND SALOL.

By JOSEPH DRZEWIECKI, M.D.,

ASSISTANT PHYSICIAN IN THE UNIVERSITY CLINIC OF THE HOLY GHOST HOSPITAL, WARSAW, RUSSIAN POLAND.

WHETHER acute primary pleurisy is of contagious origin or not, is a question that is as yet not positively decided. If, however, we consider that acute pleurisy appears rapidly and often epidemically, and, as the statistics show, it most frequently develops in winter and summer, and if we closely examine its clinical course, we must undoubtedly come to the conclusion that between the latter and all contagious diseases there exists many points in common.

These appear most strikingly if we compare acute pleurisy with acute rheumatism. In both cases the morbid process affects the tissues, which present almost the same histological structure and the same physiological function. The same injurious factors at one time produce inflammation of the pleura, at another time inflammation of the joints, or both. Thus, for instance, the so-called "catching cold" produces at one time pleurisy, at another time rheumatism, or both follow. It sometimes happens that during articular rheumatism inflammations of the pleura or endocardium appear. It has likewise been observed that during gonorrhœa sometimes inflammation of the joints, and sometimes that of serous membranes appear; at least the sudden beginning and the further clinical feature of the course of these diseases show very much analogy.

Starting from this point of view, it must be supposed that if salicylate of soda is almost always the best and surest therapeutical remedy in the treatment of rheumatic fever, it should also successfully be applied in the treatment of pleurisy.

Last year I published in a Polish paper (*Medycyna*, Nos. 44, 45, and 46, 1887) a series of cases of acute pleurisy treated by salicylate of soda, and the results which I obtained, in short, are as follows: 1, Inflammations of the pleura, on which no other remedies had any influence, subsided quickly under the influence of salicylate of soda; 2, the use of salicylate of soda within, after twenty-four hours, produced a favorable turn in the course of the disease, the prickling pain, if it did not entirely disappear, at least diminished; 3, the temperature fell; 4, the quantity of urine rose considerably, and with it also the quantity of chlorides, accompanied by diminution of pleuritic effusion; 5, this treatment was continued during two weeks, after which time the patients recovered their health again. Such a short duration of pleurisy, which generally lasts at least three weeks, speaks so eloquently in favor of the treatment of pleurisy by salicylate of soda that any further dispute on it would be needless.

This favorable action of salicylate of soda in pleurisy is by no means dependent upon its diuretic action, as some of my colleagues suppose, nor upon its sudorific action, as Eichhorst pretends, because no diuretic or sudorific remedies, which have long been employed in the therapeutics of pleurisy, are able to conquer this disease so quickly as salicylate of soda. Besides that, perspiration appears very often as well in the beginning of pleurisy, when the patient has not yet employed any remedies, as in its further development, just as in rheumatism; and in this regard we have another proof to support my opinion, that a certain relationship exists between these two diseases.

In my opinion salicylate of soda has in these cases a specific action as well as in rheumatic fever. However, I must add, that in order to obtain a good result from salicylate of soda, it must be given in large doses, two drachms daily; or, as I prescribed, a tablespoonful of a five per cent. solution every hour, till signs of poisoning appear, marked by a buzzing in the ears, and afterward a tablespoonful every two hours. I have never seen any injurious effects, such as collapse or weakness of the heart. On the contrary, I can say that in cases where the pulse was very feeble it improved considerably, which can clearly be explained by the action of the remedy in reducing the pleuritic effusion and the temperature. On the other hand, a great buzzing in the ears, loss of appetite, and a repugnance to the drug, were the constant signs that accompanied such treatment. As I convinced myself, this unfavorable influence of salicylate of soda on the stomach can be greatly diminished by giving it with milk.

Having received, through the kindness of Professor Marceli Nencki, of Berne, one kilo of salol from Heiden, of Dresden, and encouraged by the results which Bielschowski,[1] Gregori,[2] and Rosenberg[3] obtained from its use in articular rheumatism, I decided to try this new remedy also in pleurisy. I believe that the few following cases best illustrate the influence of it on the course of this disease.

CASE I. *Left pleuritic effusion.*—On August 7, 1887, I was called to a boy, aged eight, who, as his aunt told me, a week ago complained of a pain in his left side and a cough, but supposing it to be nothing grave she did not consult a doctor. In the night from the 6th to the 7th of August the boy was very restless and delirious, and this was the reason I was sent for. On examining him at 1 P.M., I found his temperature 39.8° C. (103.6° F.), absolute dulness at the back from the fifth right rib. In the beginning, when raising him up, respiration was bronchial, and, after some breathing, it became very feeble. This experiment I repeated several times with the same result. In both lungs some moist râles existed. Vocal resonance over the dull area was very feeble, as was also vocal fremitus; pulse, 148; abdomen pretty hard; stools absent since two days; tongue coated. I prescribed two powders of calomel and lactin, each two grains, to be taken in the course of an hour, and dry cups on the back. Evening temperature, 38.6° C. (101° F.); pulse, 118, and fairly good.

August 8th.—Morning temperature, 40.1° C. (104.2° F.); pulse, 148, small; physical signs unaltered; slight continual perspiration. I ordered eight grains of salol with lactin, every two hours, and milk diet. Evening temperature, 39.3° C. (102.7° F.); pulse, 110.

August 9th.—Morning temperature, 38.6° C. (99.7° F.); pulse, 90. The patient had taken ten powders; he perspired slightly; the dulness commenced from the seventh rib; friction sound present; no buzzing in the ears. He wanted to get up. Evening temperature normal; pulse, 86, and strong. The treatment was continued.

August 10th.—He took ten powders; temperature normal; the tongue almost clean; he felt appetite and continually begged to get up. Some dulness beginning from the tenth rib; respiration sounds puerile on the whole area of the lungs, only in some places some moist râles. I ordered salol every three hours, and fifteen cups on the back.

August 11th.—The tongue was perfectly clean; the patient got up and played, coughed but very little, and on the 12th of August he went out for a walk. In order to avoid a relapse I advised his aunt to give him salol every three or four hours during a few days.

CASE II. *Left dry pleurisy.*—S. W——, a gravedigger, aged thirty-five, came to consult me on the 8th of August, last year. According to his story he felt sick, after having got his feet wet a week ago. At first dry cough appeared without pain in the chest; but four days ago he remarked that when coughing and breathing deeply he felt pain in his left side. This pain, being of a shooting character, increased to such a degree that for the past twenty-four hours he could neither inspire deeply nor cough. The patient perspired continually and profusely. He then complained of a shooting pain in his left chest.

[2] Erfahrungen über das Salol, Berlin. klin. Wochenschr., 1887, Nos. 9, 10, and 11.

[3] Salol als Antirheumaticum, ibid., p. 51.

troublesome cough, and shortness of breath. On examining him I found dry pleurisy on his left side; the temperature, 38.5° C. (101.3° F.); pulse, 94; respiration, 40. I ordered fifteen grains of salol every two hours. I did not see the patient in the evening.

August 9th.—The patient took ten powders. The morning temperature, 37.7° C. (99.8° F.); pulse, 84; respiration, 26. The pain had ceased completely; friction sound not to be heard at all, even on the deepest inspiration; cough very little. Evening temperature normal; pulse, 72. Salol was continued.

August 10th.—I visited him at 1 P.M., and he told me that he had been out and felt quite well. On examining him I found no signs of pleurisy, and advised him, however, to continue salol—a powder every four hours. No buzzing in the ears during this time.

Case III. *Right pleurisy, with effusion.*—F. A——, a locksmith, aged twenty years, came into the Holy Ghost Hospital on August 13, 1887. His illness had commenced ten days before by a pain in the right chest during inspiration. He coughed from time to time, had difficulty in breathing, a dry mouth, and headache. A year ago he had, as he affirmed, a similar complaint in his left side; now he complained of a prickling pain in his right chest, cough, and headache. He was of middle stature, not strongly built, and insufficiently nourished; his family history was good. Beginning from the fourth right rib on the parasternal line, and running horizontally to the spinous process of the fifth vertebra, existed absolute dulness, and breathing sound and vocal fremitus were absent. The physical signs in the left lung were normal. Sounds of the heart quite normal; spleen and liver could not be felt. The temperature, 38° C. (100.4° F.); pulse, 96; respiration, 24. I ordered a powder of one gramme of salol every two hours.

August 14th.—In front, as well as behind, the dulness had diminished 1 ctm. Morning temperature, 37.2° C. (99° F.); pulse, 93, pretty well; respiration, 33; evening temperature normal; pulse, 96; respiration, 28. The treatment was continued.

August 15th.—Morning temperature normal; pulse, 88; respiration, 28. Pain in the side ceased. The dulness had still further diminished; feeble respiration sounds could be heard; no buzzing in the ears. The treatment the same.

August 16th.—The temperature normal; pulse. 80; respiration, 24. Dulness in the front absent, behind it began from the eighth rib; friction sound audible; the quantity of urine, 450 c.c., specific gravity, 1.030, of dark-green color, without albumin or sugar. Treatment the same.

On August 21st the patient was discharged cured.

Case IV. *Left pleurisy, with effusion.*—P. L——, a house-painter, aged forty-eight years. He said that he had "caught cold" two weeks previously, and then had fever, violent headache, and vomiting, followed by dry cough and pain in the left side of the chest. He took a purgative, and was cupped on the left side behind which gave him some relief for a short time, but the pain increased afterward, and dyspnœa appeared, and on August 6th he sent for me. Examination showed temperature 38.9° C. (102° F.); pulse, 120; respiration, 38; absolute dulness on the left side in the axillary line on the sixth rib; behind, it began from the lower angle of the scapula; over the dull area bronchial respiration could be heard; vocal fremitus absent; the tongue was coated, bowels open. Salol was given in one-gramme doses every two hours.

August 7th.—He took ten powders of salol. The morning temperature, 37.8° C. (100° F.); tongue somewhat cleaner; dulness diminished 1.5 ctm. behind, and 1 ctm. in front. The pain considerably less. Evening temperature, 37.2° C. (98.9° F.). Salol was continued.

August 8th.—The temperature was normal; dulness commenced from the eighth rib; friction sound audible. Salol was continued every two hours.

August 9th.—He had no buzzing in the ears; he had some appetite and felt tolerably well; dulness from the ninth rib; friction sound plainly audible. Treatment the same.

August 10th.—Respiration sound normal; friction sound could still be heard, but only during deepest inspiration. Salol was continued every three hours.

August 12th.—The patient returned to his work, being completely recovered.

Case V. *Right pleurisy, with effusion.*—J. K——, aged twenty-four, a locksmith, came to the out-door department of the Holy Ghost Hospital on August 18, 1887, complaining of a pain of shooting character in the right side of the chest, cough, feebleness, and violent perspiration. As he said, he had become ill two weeks before, after "catching cold." He took a Roman bath and purgatives without any relief. His family history was good. On examining him I found absolute dulness, commencing from the right spine of scapula. On the dull area bronchial respiration existed; vocal fremitus was absent. The temperature, 37.9° C. (100.2° F.); pulse, 124, a little feeble. I ordered one gramme of salol to be taken every two hours.

August 19th.—I saw the patient at 1.30 P.M.; he had taken ten grammes of salol. The temperature was normal, the dulness diminished 1.5 ctm., the skin moist. I ordered to continue salol.

August 20th.—He took ten powders of salol; no buzzing in the ears. The dulness commenced from lower angle of scapula. Respiration sound very feeble; the tongue cleaner; temperature normal. The treatment was continued.

On August 25th the patient was well.

Case VI. *Articular rheumatism; large right pleuritic effusion, endo- and peri-carditis; recovery.*—J. M——, a servant, aged twenty-four, well nourished and strongly built, was admitted into the Holy Ghost Hospital under my care on August 26, 1887. According to her the illness commenced, after catching cold, ten days before she came under observation, with an attack of fever, headache, pain in the throat, and in the joints. In spite of her illness she walked about and worked, but in the evening the pain increased to such a degree that she was obliged to go to bed. On admission her pulse was 105, full, quickly disappearing; temperature, 39.8° C. (103.6° F.); tongue coated, but moist. She complained of shortness of breath, cough, and pain in the joints, aggravated by movement. On examination the right chest, from the lower angle of the scapula was found to be dull on percussion. Bronchial respiration was heard over the dull area; movement was much diminished and vocal vibration was abolished. The dulness of the heart was increased toward the left; the apex-beat was found in the fifth space, about half an inch outside the nipple. On auscultation the sounds were feeble, with a prolongation of the first sound at the apex; to-and-fro friction sounds were audible at the third left space. Pulse was quickened. The joints were œdematous and painful when touched, especially the knees and heels. Salicylate of sodium was ordered, a blister was applied every other day, and the bowels were kept open. The following days the temperature did not fall; in the morning it was 38° C. (100.4° F.), and in the evening never below 39° C. (102.2° F.); pulse from 105 to 120, full and rapid. The patient was lying on her right side, and this position was most convenient; on changing the position she suffered from dyspnœa, pain in the right chest, and palpitation.

August 31st.—Pericardial friction disappeared, the heart's sounds obscure, but without any murmur. Dulness of the heart increased a little—it began from the third rib—as likewise dulness of the right chest, which began from the spine of the scapula, and in front from the fourth rib. The articulations were painful. She commenced to spit blood, and complained of more violent cough. The morning temperature was 39° C. (102.2° F.); evening, 40.3° C. (104.5° F.); pulse, 134, feeble. From the fact that the patient continually lay on her right side, the bloody sputum was regarded as the consequence of hypostatic pneumonia. Digitalis, and a blister on the cardiac region were ordered. By this treatment she not only obtained no relief, but, on the contrary, every day it could be observed that she became worse, so that on September 6th she was without strength; her pulse was 132, very feeble; the eyeballs sunk; temperature, 39.9° C. (103.8° F.); physical signs without change. All my colleagues who observed the patient believed that she would die in less than two days. Instead of giving stimulants, I prescribed fifteen grains of salol every two hours, and a blister on her right side behind, and also on the cardiac region.

On September 7th she took seven powders of salol and felt better; the pain in the articulations and in the chest was less; pulse, 116, and better, although it was still feeble; evening temperature, 38.6° C. (101.5° F.) Salol was continued.

On September 8th she took eight powders of salol. The absolute dulness of the right chest began from the lower angle of the scapula. The sputa was still bloody. Morning temperature, 38.2° C. (100.7° F.); pulse, 102; evening temperature, 38.6° C. (101.5° F.).

September 11th.—The temperature was normal; pulse, 96; dull area of the heart from the fourth rib; the cardiac sounds clear. She slept well; sputum, mucus. Behind, some dulness from lower angle of right scapula. Respiration sound very feeble; slight vocal vibration could be felt. From this time the remaining physical signs of pleurisy began to disappear pretty quickly, so that on September 27th the patient was able to leave the hospital, being quite recovered.

Remarks.—From the results obtained in these few cases, it may be concluded that in salol we possess a more valuable agent in the treatment of pleurisy than in salicylate of sodium. Possessing all the positive qualities of salicylate of soda, it is free from unpleasant effects of the latter; viz., it very rarely produces buzzing in the ears, and even being employed for a long time does not spoil the appetite, which is a very important thing, and does not produce any feebleness of the heart, nor collapse. However, I must draw the attention to this, that in order to receive a quick effect from salol, it must be given in large doses, from eight to twelve grammes (ʒ ij.–iij.) daily. Smaller doses, as half a gramme, even given often, have no such good action.

I have noticed that some of my colleagues, after having given only three or four grammes of salol to patients with rheumatism, become uneasy on account of the dark color of the urine, which was preserved in order to show it to the doctor. The dark color of the urine can only then be considered as a symptom of poisoning when present in fresh urine, as the urine of every patient who takes salol will, after standing in the air, turn black. As to myself, I went as far as twelve grammes daily, and I never saw any symptoms of poisoning. According to Professor Nencki, of Berne, the maximum dose is thirteen grammes, and although it has been observed that even twenty grammes of salol daily did not produce any symptoms of poisoning, yet this fact must be explained by the circumstance that the drug in these cases was not entirely absorbed. Finally, I must add that, as in rheumatism there exist cases on which neither salicylate of soda nor salol has any action, it must be supposed that also similar cases of pleurisy can be found which will not yield to such treatment. In one word, all that has already been said about salol in the treatment of rheumatism can also be equally said of the treatment of pleurisy.

21 Stare Miasto.

Santonin in Amenorrhœa.—Dr. Whitehead recommends santonin, in ten-grain doses at night, in the treatment of amenorrhœa, and says that he has seldom seen the drug, given for several nights in succession, fail to relieve this condition.

THE VALUE OF CONDENSED MILK AS A SUBSTITUTE FOR MOTHER'S MILK.

By S. HENRY DESSAU, M.D.,

PHYSICIAN FOR DISEASES OF CHILDREN, OUT-DOOR DEPARTMENT, MOUNT SINAI HOSPITAL.

A prejudice toward the use of condensed milk as an article of infant's food, or, more properly speaking, as a substitute for mother's milk, has long existed among certain physicians of this city, who are recognized over the entire country as authorities in the diseases of children. The views of our city physicians are justly held as exerting a high influence upon the professional mind of the surrounding country, and it is for this reason that I desire, more especially at this time, when the question of the best substitute for mother's milk is of the highest importance to our infant population, to direct attention to condensed milk as an article of infant food, for the purpose of endeavoring to correct some of the false impressions entertained against its more general use. It may be stated at the outset that there are two kinds of condensed milk made in this city by the Borden, Canfield, and Eagle Companies, known as the *plain* or fresh, and the *preserved* or canned. The associations connected in the mind of many practitioners with the use of the latter may account in a large measure for the unfavorable opinion held concerning the value of condensed milk. It is to the plain, or fresh variety, that is served daily from the company's wagons that I wish to direct attention. It is unanimously conceded by recognized authorities that cow's milk is the best and most available substitute for the mother's milk. The objections to its general use, however, are that, during the summer months, it is impossible to obtain it fresh and unadulterated in large cities, unless at a cost beyond the reach of the masses. All of the milk that is delivered in this market is at least from twelve to twenty-four hours old, and has undergone rough transportation of from fifteen to thirty miles in not strictly clean vessels. I am informed that the cans used in bringing the milk to the city are not cleansed until returned to their owner. By the time that the milk has reached the poorer classes, it has commonly undergone more or less adulteration, often in spite of the closest watching by the health-authorities. In the course of its consumption by the average infant, it is still further liable to lactic-acid fermentation, and even though boiled, it is not unlikely to become scorched or made otherwise unwholesome for the infant.

Perhaps the most important objection to cow's milk, notwithstanding the fact that it is regarded as the nearest approach to mother's milk, is the *difficult digestion of the casein* by the delicate infant whose stomach has been damaged by an attack of summer diarrhœa. This has necessitated the invention of numerous means and measures for overcoming the obstacle, the most common of which is the addition of some farinaceous substance. Such practice, I hold, for an infant previous to the eruption of its teeth, is contrary to the provisions of Nature, and, though occasionally successful, cannot be defended as a general usage upon physiological principles.

For infants living in small communities, where a fair quality of cow's milk can be procured fresh, these objections need not apply; provided that a reasonable amount of care is observed in keeping the various utensils for holding the milk clean and the milk cool.

In view of these many deficiencies, there can certainly be no valid reason against the more general use of the plain condensed milk, as a substitute for cow's milk, for infants living in large cities, when the manner of its preparation is more widely known. In the first place, it is impossible to adulterate condensed milk. The quality and purity of the milk employed in its manufacture, especially that of the Borden, or New York Company, is of the best. The milk used is delivered under strict contract; besides that, the various dairies are frequently inspected by agents to see that the terms of the contract are not violated. This milk, obtained from a large number of cows, presents an average quality that renders it far preferable to the milk of one cow only. Contrary to the statement of some writers on this subject, no cream is removed from the milk before condensing. In the process of condensing, the milk is exposed for an hour or more to 210° F. of heat under pressure, which, according to Soxhlet, is sufficient to destroy any germs it might possibly contain, thereby rendering it practically sterile. At the same time, and this is a point that I wish to be regarded, the condensing process *alters the casein* in such a manner that it appears, when properly diluted thereafter, to coagulate in the infant's stomach more like the casein of mother's milk; that is to say, in light flakes, instead of the firm, hard masses into which we sometimes see the casein from ordinary cow's milk coagulate. When the plain condensed milk, which contains *no cane sugar* to preserve it, is kept in an ice-box or refrigerator, it will remain fresh for from two to six days, which is long enough for all practical purposes. Compared with cow's milk, made sterile according to Soxhlet's method, it is far simpler, as the latter must prove complicated in its process of preparation in the hands of the ignorant and careless.

A not unimportant advantage in favor of condensed milk is the fact that it can always be *diluted in any desirable proportion*, to suit either the age of the infant or the powers of its stomachal digestion. It is never known how much ordinary cow's milk has previously been diluted. It has been urged as an objection to the use of condensed milk that it requires too much dilution, it being supposed that it has been reduced one-fifth in bulk. Now it is a well-known fact that the first thing advised in the use of cow's milk for infants under six months of age is to dilute it one-half with water. Condensed milk will require four parts of water to bring it to the standard of fresh cow's milk. If this is now diluted again one-half, we would have to use altogether seven parts of water to one of condensed milk for an infant under six months of age. As a matter of fact, I have found in my experience, which is not altogether a small one, that a dilution of one part of condensed milk to *sixteen parts of water*, is the proportion most easily digested, and it agrees in every way best with the young infant. After the age of six months I am in the habit of increasing the condensed milk from one-half to double the quantity. It is true the urinary functions are kept active, but that is all the better. Water is as necessary for the perfect assimilation of food in the infant as in the adult, and the mistake is commonly made of withholding it where it should be given.

Then it is said that though a child thrives on condensed milk, if it becomes ill it loses fat rapidly. This idea may apply to the preserved or canned condensed milk, which is only fit for use on ships and in armies; but as to the plain or fresh condensed milk, there are certainly no just grounds for such statements. The elements of nutrition are precisely the same as in fresh cow's milk; the amount of water is the same as it is commonly prepared; there is *no addition of sugar*, as is usually the case when fresh cow's milk is prepared for infants; and, finally, in a large observation of many years, I have not witnessed such results. That is to say, infants fed upon plain condensed milk do not lose fat any more rapidly than infants fed upon the breast or fresh cow's milk, when taken ill; and, it will be remembered, I advise a larger dilution than that compared with the ordinary preparation of cow's milk.

Condensed milk is certainly as simple and easy to prepare as cow's milk, and even safer; for it requires more care and labor to keep vessels used in the preparation and boiling of cow's milk, to which sugar has been added, clean, than it does to clean a cup that has simply contained a mixture of water already boiled, and the condensed milk.

Certainly I insist upon strict attention to the preparation of the condensed milk as a food for infants, irrespective of the season of the year. I direct a tablespoonful of the plain condensed milk to be added to a teacupful (equivalent to eight ounces) of water that has been previously boiled and allowed to cool to about 100° F., and a pinch of table salt is added. I prefer giving it from a graduated nursing-bottle, and instruct the nurse to scald out the bottle immediately after using, and to keep it filled with a solution of borax, when not in use. The nipple is likewise kept in a glass filled with the solution of borax. As with natural-fed infants, the hours for nursing are systematically arranged and strictly adhered to, unless the infant will go longer than the schedule time which is allowed.

As I have endeavored to present the case in favor of condensed milk, I fail to see what reasonable objection can be offered to its use, referring, as I have before shown, to the plain or fresh variety; while I see, as I hope this article may help others to do, many reasons why it is superior to ordinary cow's milk as obtained in this city and others of large size. If there were establishments for its preparation in all of our larger cities, I am convinced that it would be a blessing both to infants and parents.

47 West Fifty-sixth Street.

Progress of Medical Science.

Parasites in Fish.—Among the more recent discoveries of scientific research is that of the presence of parasites in fish. Of these tiny eel-like creatures ten kinds are recognized in the fish of the Mediterranean Sea, the Atlantic and Indian Oceans. They are generally found in some hollow part of the fish's body, the cavities of the star-fish's respiratory organs being a very favorite abode. Sometimes, however, they attach themselves to a part of the fish where life is not so easy a matter for them; for instance, they have been found in a pearl-oyster, buried in a curl of the shell. These parasites do not endanger the life of the fish on which they live, as they feed on the microscopic organisms which are washed into the cavities of the fish by the sea-water—eating their messmates, as Van Beneden says.—*The British Medical Journal.*

Hysterical Eye Symptoms.—At a recent meeting of the London Ophthalmological Society, Dr. Griffith read a paper on "Functional Eye Symptoms in Hysteria" and allied conditions. He classified the cases into the following groups: 1. Hysterical blindness, mostly monocular. 2. Amblyopia of one eye, with achromatopsia and hemianæsthesia (Charcot). 3. Same group with absence of hemianæsthesia. 4. Blepharospasm as sole eye symptom. This symptom was common in all the groups. 5. Hysterical conjugate deviation of eyes. 6. Neurasthenic asthenopia, symptoms bilateral. He was in favor of the theory of changes in the centres of vision rather than in the retina, as the cause of the contraction of the field of the vision.

The Treatment of Spinal Abscess.—At the Harveian Society (*The Lancet*), Mr. Watson Cheyne read a paper on the "Treatment of Spinal Abscess." In these abscesses the contents, the wall, and the lesion of bone from which they start are to be considered, although the latter cannot always be made out. Three types of tubercular disease were described: 1. Tubercular cavities containing soft cheesy material; 2. Tubercular sequestra, either unseparated or in cavity lined with tubercular granulations; and 3. Superficial caries of bone. Curvature is commonest in the first class, but the last is the most extensive, and is chiefly found in adults accompanied with abscess. The contents of these abscesses is not true pus, but broken-down cells and tissues floating in a variable amount of fluid. This fluid produces, when inoculated, tuberculosis in guinea-pigs. The pyogenic organisms take no part in the production of the chronic abscesses, but grow freely in their unexhausted contents, and therefore the entrance of putrefactive ferments into their cavities causes septic intoxication and chronic osteo-myelitis of bone. Two methods of treatment were considered: One, in which the abscess was cured without opening it, and by the injection of iodoform and glycerine, or iodoform dissolved in ether; and the other method by antiseptic opening. Statistics of fifty-six cases were given, of which 73.2 per cent. healed and 12.5 died. These were mainly psoas abscesses, but dorsal, lumbar, and cervical were included. Cases were most numerous between twenty-eight and thirty years of age.

THE TONGUE AS AN INDICATION OF DISEASE.—In this year's Lumleian Lectures, delivered by Dr. W. Howship Dickinson (*The British Medical Journal*), the subject indicated by this title was discussed at great length. The author states that the knowledge which enables many a practical physician to make the tongue an index of diagnosis, treatment, and prognosis is, for the most part, unwritten. It has been handed down to us as part of the tradition of the elders, and few attempts have been made to analyze or educe laws from the accumulation of experience of which it consists. The labor which has been bestowed upon the pulse is in remarkable contrast with the neglect which, in recent times, has been the lot of the tongue. Of late the tendency in this matter has been to agnosticism; it has become the habit with many, and those not the least influential, to look upon the changes which this organ displays as of less and less importance, to regard them as accidental rather than essential, as the results of unimportant local conditions rather than as inseparably connected with constitutional disturbances. "The tongue," said a great surgeon, "belongs to the mouth in the first place, and to the general system only in the second." Dr. Dickinson would put the general system first.

The following is the author's

Classification of Tongues.

Naked Eye.	*Microscopic Description.*
1. Healthy. Moist.	White epithelium in small amount on papillæ, not continuous or superabundant.
2. Stippled. Moist. Dotted with white.	Excess of white epithelium on papillæ, not extending between them.
2 (D). Stippled. Dry.	Ditto.
3. Stippled and coated. Coat continuous in parts. Moist.	White epithelium on papillæ in excess, with partial filling of intervals.
3 (D). Stippled and coated. Dry.	Ditto.
4. Coated white. Moist. Coat continuous.	Excess of white epithelium on papillæ. Intervals more or less filled up with epithelium and accidental matters.
4 (D). Coated white. Dry. Coat continuous.	Ditto.
5. Strawberry. Coated and injected, especially showing in fungiform papillæ.	Like the coated or plastered, but with more injection.
6. White, plastered. Thick uniform coat, abrupt and striking.	More elongation of papillæ than with coated tongue; more filling of intervals, with superficial accumulation.
7. Furred or shaggy. Moist. Greatly elongated papillæ.	Extravagantly long papillæ, mostly of horny epithelium.
7 (D). Furred or shaggy. Dry.	Ditto.
8. Encrusted, dry, brown. Thick felted dry coat over papillæ.	Continuous crust on and between papillæ, largely of parasitic matters.
9. Furred or encrusted, becoming bare. Generally dry	Crust breaking away, together with more or less of normal surface.
10. Denuded. Red. Absence of normal covering.	General absence of all epithelium excepting the Malpighian layer; sometimes of that also.
11. Red. Moist. Dry membranous covering.	Level membrane replacing epithelial processes.
12. Cyanosed.	Injected; hypernucleated; excess of deep epithelium.

Dr. Dickinson sums up his conclusions as follows: The tongue is an index of constitutional states, seldom of individual diseases. An ancient theologian described the face of a wicked man as a map of the empire of sin. It has been fancied that the tongue presents a map of the empire of disease; and a writer, though one of no great note, has gone so far as to divide the lingual surface into a number of rectangular regions as numerous as the United States of America, which he places under the rule of separate organs; the larynx, the bronchi, the lungs, the pleuræ, the large intestine, the small intestine, the kidneys, and the brain each possessing a distinct territory. The heart, says this writer, very wisely, has a common control over all. But, in truth, the tongue has no such local signification; it seldom points to solitary organs or isolated disorders, but is rather a gauge of the effects of disease upon the system than an indication as to the locality of it. It is often a guide in treatment, so far as treatment is general, not local; and it is an important help in prognosis. It may, indeed, be doubted whether any means of observation open to the physician, including the pulse and the thermometer, give him more insight into constitutional states than he can derive from the tongue. Clinically, it always speaks the truth, and in a language which is not foreign to the experienced physician.

It has been shown that the white coat of the tongue essentially consists of horny epithelium, and that the various grades of coating are mainly due to its increase. It has been shown that the several degrees of coat are mainly due to overgrowth of epithelium, though in a smaller measure to its want of removal, and that there is a remarkable correspondence between the heat of the body and the coating of the tongue. If the tongue be coated, the indication is usually of febrile disturbance without especial reference to the stomach or liver, and points more to the general system than the alimentary. Though something is to be ascribed to disuse, yet I think I have shown that too much has been; and that more than one modern observer, like an uncharitable pedagogue, has attributed to idleness what is directly due to illness.

Superadded to the *forcing process*, if I may so speak, of fever, we have step by step other changes—dryness, furring, and encrustation—which are essentially connected with want of saliva. I have endeavored to show that this diminution or arrest is declared by the state of the tongue almost as certainly as by observations on the ducts, and is the chief cause of the furring and encrustation which accompanies it. It is true that in the crust are parasites, but these are secondary; the primary fact is the want of saliva, a clinical indication always of importance, though the process by which it is brought about is not always the same. I have shown the effect of dehydration in diabetes and by diarrhœa; but it has, I think, been made clear that the most frequent and important concomitant of the dryness is a certain failure of bodily force and function which I have not assumed to describe with physiological exactness, but have expressed by such terms as weakness, prostration, and exhaustion. I do not ignore the effects of deprivation of water, of alcohol, and of opium; but, nevertheless, the relation to which I have drawn attention, so far as it concerns such dryness as to cause encrustation, has a general hold. It is difficult not to infer that with the salivary are other glandular failures, more especially such as concern the digestive system. Good digestion waits on appetite. Putting aside diabetes, where there are special circumstances, it may be said with general truth that with the dry encrusted tongue appetite is *nil*, and solid food impossible, not merely from the local difficulty caused by the dryness of the mouth, but from inability more profoundly seated. It may be inferred without rashness that the loss of power to take food is connected with a loss of power to assimilate it; and if the digestive function is in abeyance it is not likely that the digestive fluids are abundant. Hence it presents itself as what may be called a working probability, that a want of the more vital juices concerned in nutrition may be indicated by the want of saliva which is sometimes so conspicuously displayed. Physicians acknowledge in their practice some such guidance; the dry and encrusted tongue is seldom disregarded as a call for animal liquids, which require little digestion, and alcohol, which requires none. To translate theory into practice is not only dangerous because the theory may be wrong, but the means may be ill-adapted, though the theory be sound. I have often taken the dry tongue as an indication for peptonized food, and thought it beneficial, but have not as yet had enough experience to speak confidently.

Proceeding from the varieties of clothing which dryness produces, we come to the opposite, but sometimes succeeding, condition—that of nakedness. This is often connected, like the previous, as has been shown, with want of saliva, of which it is usually a latter concomitant. It may be simply due to this cause, but other circumstances are so often present that it is difficult not to assign to them some share in the loss of integument, and attribute this, in part at least, to the failure of nutrition which belongs to hectic fever and suppurative waste. When the tongue becomes dry and bare it is ill with the patient. He is not sure to die, but likely to. If, as has been said, the tongues of dying men enforce attention, it must be often directed to this. The indication of the red, smooth tongue is for what failing nutrition calls for—tonics, stimulants, and food, probably liquid, but nourishing. The failing pulse does not more surely tell of asthenic tendencies than, as a rule, does the red, dry, and polished tongue.

The tongue, indeed, has a whole book of prognostics written upon its surface. When the tongue is approaching the condition of health, so, as a rule, is the patient, as is seen whenever the red, dry, and bare tongue acquires moisture and clothing. There is no better sign in diabetes than the resumption of the natural moisture by the tongue which has been dry. Something may be judged by the way an incrusted tongue cleans; if gradually and from the edges, well; less so when in scales, especially when the surface exposed is red and dry. One glance at the coated or plastered tongue may give an assurance, which perhaps could not be otherwise obtained, that the disease is on the wane. If the thick coat in the centre steeply shelves toward the sides and front, revealing a normal, moist, not over-injected surface, the tongue is in process of cleaning; the natural friction is overcoming the coating process, and tongue and patient are on the mend.

Opposition to the Alcoholic Treatment of Disease.—In a recent paper on "The Difficulty of Diagnosis between Disease Symptoms and Drug Symptoms" (*The British Medical Journal*), Dr. Alfred Carter condemns alcoholic treatment in the following terms: It is far better to allow disease to run its course in a natural way, and to pilot the case through the blood storms which the disease may be setting up, rather than by rendering the nervous system less sensitive to the influences of disease by deadening the activity of those nerves, and while so deadened, allowing disease to establish itself, and so organic change may take place, never to be entirely removed. This appears to me to be the effect of the alcoholic treatment of disease. It is better for the patient to endure the discomfort, and ultimately get quite well, than to be comforted, as it is called, by the use of intoxicating liquor, and so allow real disease to gain a standpoint, instead of treating the upset which arises from the functional disturbance caused by the determination of natural laws to assert their predominance, and so to lead to a perfect cure.

Acute Periosteal Swellings in Several Young Infants of the same Family, probably Rickety in Nature.—At a recent meeting of the London Clinical Society (*The Medical Press*), Dr. Samuel West read a paper on this subject. A child, five weeks old, was brought by its mother, with the statement that its left arm had "dropped." A swelling, apparently periosteal, occupied the middle third of the shaft of the left humerus. It was exquisitely painful and tender. The movements of the arm were perfect, but the child kept the arm still on account of the pain which movement caused. Similar swellings were found on the right humerus and on the left femur. There were some slight bosses on the ribs, but no other signs of rickets, and the child was well developed and well nourished, and, except for the pain of the swellings, seemed in good health. The treatment consisted in the administration of some cod-liver oil and a little iodide of potassium, and the mother's milk was supplemented with cow's milk. In a fortnight the pain had almost gone, and the swellings were smaller. In the course of three months they were hardly to be made out, and they ultimately entirely disappeared, leaving the bones straight. The patient was the fifth child, born at the eighth month, and fed upon the breast only. The first swelling came on the ninth day, the second on the fourth week, and the last two days before it came under observation. Of the other children the eldest was similarly affected at the age of a week. The child, now a lad of nine years of age, was seen, and showed no traces of the old bone affection. The second, a boy, now seven years of age, was never so affected. The third, a girl, now five and a half years of age, and also the fourth, a boy, now three and a half years of age, were both affected, the former recovering completely, but the latter had considerable rickety deformity. There was no history of syphilis, or evidence of it, in the family. The second case was seen in a child of the brother of the father of the previous children. It was a girl-infant of three weeks old, and had developed a swelling of the left humerus a week before being seen. It was also suckled, and as the mother was strong, no medicine was given and no treatment adopted except to keep the arm still by a loose bandage. In about a month the swelling had entirely disappeared. This patient was the fourth child. The first, a girl, aged six, and the third, a girl, aged two, were, and had been, always well. The second, a boy, aged four, had had both arms and legs affected in the same way at the same age, but had got quite well. In this case also there was no evidence of syphilis. Dr. West believed that all these cases were rickety in nature, and closely allied to acute rickets, if not actually cases of that disease. From the cases of acute rickets recorded they differed in respect of age, acute rickets being rare in so young children; also in the fact that more than one member of the family was attacked; and lastly in the mortality. That these were cases of early rickets cannot, however, be doubted, on account of the evidence of rickets in the family, and of the absence of any other assignable cause. Of syphilis there was no other evidence, and green-stick fracture or injury must also be excluded. Dr. West also referred to another case seen by him, and recorded by Mr. Herbert Page, which was an undoubted case of acute rickets, and that seemed to him to differ from those here described only in degree. The element of scurvy had been supposed to enter into the causation of acute rickets, but that condition was certainly not existent in the present cases.

Antipyrine in Labor.—M. Queirel, of Marseilles, has pointed out the alleged good effects of antipyrine in labor. He administers it subcutaneously in five-grain doses. He says that in about twenty minutes after the injection the pains become much less severe, and in two hours the dose may be repeated. The contractions continue regularly under its influence, and when the moment of expulsion arrives the woman seems to suffer but very little. Of twenty cases treated in this manner fifteen were greatly benefited. The remaining five were refractory, four of them being primiparæ.

Electrolysis in the Treatment of Resilient Stricture of the Urethra.—The treatment of urethral stricture by electrolysis appears to be finding more favor recently than was accorded to it not many years ago. In *The Medical Press*, Dr. F. S. Edwards, of the West London Hospital, records a series of twenty-four cases treated by the electrolytic method. He observed only three failures among the two dozen. He makes the statement that the only disadvantage attaching to electrolysis is the time it takes, whereas its advantages are many, viz.: 1. No confinement is necessary. 2. No risk to life. 3. No pain, and only sometimes slight discomfort. 4. No bleeding. 5. If unsuccessful it does not interfere with urethrotomy being undertaken forthwith. 6, and lastly, a cure (permanent) may follow, which is the rarest thing by any other method. He concludes that electrolysis is of the greatest use, in strictures of small calibre, to facilitate the passage of a urethrotome, and in impassable strictures to render the passing of bougies possible, if for some reason or other electrolysis is not persisted in. The more recent the stricture and the more it approaches the ring variety the better the result. In his experience electrolysis does not appear to answer in meatal strictures, but these can so easily be cut. He would suggest that strictures, of whatever variety, when situated in the deep urethra, and which are not amenable to treatment by dilatation, should be subjected to electrolysis before any cutting operation is thought of. He excepts cases calling for an immediate restoration of the calibre of the canal, as in stone, etc. In saying this he does not wish to depreciate internal urethrotomy. No one values it more than he, and the risks attending it are now reduced to a minimum, the mortality being under three per cent. in his hospital. Yet there is a risk, and a fatality may occur when least expected, and where most to be deplored. In electrolysis, as far as he has seen and heard, no risk whatever is run.

Turpentine in Surgery.—The oil of turpentine is recommended as an application to all cases involving a solution of surface continuity from injury. In severe wounds of the hand or other parts, involving extensive laceration, the oil is said to prevent suppuration and sepsis, and so conduce to rapid recovery. In such cases the parts are well cleansed with hot water, and pledgets of lint steeped in the oil are applied. The dressing is kept saturated with a mixture of two parts of the oil of turpentine and one of linseed oil.—*The Medical Press.*

Ligature of the Thyroid Arteries in Goitre.—In speaking of this subject Professor Billroth says that the reason we are not content with the results of extirpation in goitre is because we are not always able to prevent tetanus, because the recurrent laryngeal nerve may be cut or tied, and because "cachexia strumipriva" is not always avoidable (*The British Medical Journal*). As after ligature of the thyroid arteries small arteries still supplied the goitre with a certain quantity of blood, it was probable that no gangrene, but only a gradual shrinking, would take place, just in the same way as in the case of obliteration of the renal artery. The small arteries, which in this case derived their origin from the renal capsule, hindered the occurrence of gangrene after the obliteration of the renal artery, but they were not able to prevent atrophy supervening in the kidney. Though this analogy was very striking, the matter, nevertheless, required to be verified by experiments on animals and men, which was also done by Wölfler. The indications for this operation were, nevertheless, limited, as extravasation, calcification, cystic and colloid softening were very often met with in goitres, which, owing to the absence of any circulation in them, would, of course, undergo no change whatever after the ligature of the thyroid arteries. The question as to whether the fluid contents of cysts were capable of undergoing absorption after operation had yet to be decided. It thus became evident that the method in question would be really successful only in those cases in which no degenerative necrobiotic processes had yet taken taken place, such as rapidly growing goitres in young subjects. Two points were necessary for the success of this plan: 1. The first effect after ligature of all four arteries was that of a glandular anæmia; the goitre would be smaller and softer than before operation. 2. The second effect was obliteration of the blood-vessels, and the disappearance of the epithelial and interstitial tissue, so that only cicatricial connective tissue would remain behind. Respecting the development of "cachexia strumipriva" in children after complete atrophy of the thyroid gland, Professor Billroth considers that no positive statement could be made on this subject, but that it was possible that such a condition would not supervene, as the atrophic process, in such a a case, took some weeks or months to become complete, and the organism had thus sufficient time to get accustomed to the absence of the thyroid gland. As to whether it was probable that the atrophy would be permanent, Professor Billroth holds that, when all four arteries are ligatured, there could be no doubt about this, but that, when circulation still existed in one of the chief arteries, or became established again by the "vasa vasorum," such a permanent atrophy would never occur. This had already been confirmed by experience. Discussing the details of the operation, Professor Billroth states that, in his opinion, the incision on the outer margin of the sterno-mastoid muscle was the most convenient one for ligaturing the inferior thyroid artery; he wished, however, to lay stress on a point which had not yet been mentioned, namely, the extreme thinness and fragility of the inferior thyroid artery. It had occurred to him on three different occasions that this blood-vessel was torn by the manipulations with the forceps or by ligaturing too fast, etc. The hemorrhage which thus ensued was very considerable, and it was very difficult to pick up the artery which retracted behind the scalenus muscle. In one case he cut through the scalenus muscle to enable him to seize the end of the artery with a broad clamp. In ligaturing arteries Professor Billroth usually applied two ligatures in their continuity, dividing the vessel between them. In the above-mentioned operation, however, he contented himself with one ligature, owing to the fragility of the inferior thyroid artery. He had never met with secondary hemorrhage in such cases. Professor Billroth has performed the operation in question in four cases of common goitre. In all of them there was a slight degree of fever, of short duration, but the absorption of the substance of the goitre was not attended with any ill effect on the general condition of the patients. The impression which the operation had made on him was a very favorable one, and he would repeat it in appropriate cases, but in future he would ligature all the four arteries at one sitting. In one of the cases thus operated upon he observed a slight degree of jaundice, which soon disappeared, and was probably due to absorption of the blood. From a cosmetic point of view it had to be borne in mind that the ligature of all four arteries naturally caused four scars, as against the single lateral scar left after extirpation, which could easily be hidden by a small cravat. On the other hand, the attenuated appearance of the neck from which the thyroid had been removed was a still greater disfigurement. Professor Billroth concludes by stating that although ligature of the thyroid arteries was a valuable and interesting addition to our operative resources in the treatment of goitre, it would have a much greater importance if it were attended with similar results in the case of sarcoma and carcinoma of the thyroid gland.

Cholesterine Crystals in the Retina.—At a late meeting of the Liverpool Medical Institution (*The Medical Press*) Dr. Grossmann showed two cases with crystals of cholesterine in the retina. In the one case, that of a young woman, aged twenty, the ophthalmoscopic image was a very beautiful one. There was to be noticed first an oldish hemorrhage in the region of the yellow spot; besides this, the retina was detached in various places, principally toward the equator. On closer inspection the region between the yellow spot and disk (and surroundings) showed a number of very brilliant crystals, changing their bright yellow light with every movement of the ophthalmoscope into green and blue. Some of these crystals were situated just in front of a retinal vessel, leaving no doubt about their position in the retina. The other patient, a man, aged thirty-five, showed a few large crystals, but an otherwise healthy retina. In both patients the urine had a specific gravity of 1.030 to 1.032 on an average, without albumen or sugar, but rich in urates and phosphates.

Loose Body in the Elbow-joint.—Dr. G. Boeckel relates this case: The patient, a strong, healthy man, aged forty-five, fell from a ladder on his left elbow. Immediately after the accident he lost all power of movement in the forearm. When he came under Dr. Boeckel's care, some two months later, movement was found to be very limited and painful, both pronation and supination being accompanied by grating in the joint. Between the olecranon and the external condyle of the humerus a hard body was felt projecting slightly, which could be moved laterally to the extent of some millimetres. Dr. Boeckel was under the impression that he had to do with a case of old arthritis deformans, which the injury had started into renewed activity by displacing an osteophyte. He cut down on the loose body, and with considerable difficulty removed it, when he was surprised to find that it consisted of half the head, with a small piece of the neck, of the radius. The patient made an excellent recovery, and in three weeks from the date of the operation had so far regained the use of his limb that he was able to do light work with it. Dr. Boeckel said that this was the first case he had met with in which the loose body was a fragment of articular surface broken off by violence, and he took the opportunity of formally recanting a different opinion to which he had recently committed himself on the subject. In fact, less than a year ago he had maintained that such a mode of origin was inadmissible, the loose body being in all cases formed by vegetations springing from the synovial membrane or the articular cartilage.—*Gazette Médicale de Strasbourg*.

THE PHENOMENA OF DEATH BY DROWNING.—Dr. Paul Loye has published some observations made by him, bearing on the phenomena which precede death by sudden immersion. The first stage of deep inspirations lasts about ten seconds, followed by a reaction caused by the resistance to the entrance of water into the bronchioles. This lasts for a minute, and is succeeded by arrest of respiration and loss of consciousness. Finally the scene closes with four or five respiratory efforts—the last. Immersion causes an immediate rise in the blood-pressure, with slowing of the heart-beats. The action of the heart remains slow but strong till death ensues. The pressure gradually lessens, but rises just before death, to fall to zero immediately afterward. The heart sometimes continues to beat feebly for about twenty minutes. The result is the same in animals which have been tracheotomized; the period of respiratory resistance is, therefore, due to the respiratory muscles, and not to spasm of the glottis.—*The Lancet*.

TRANSPLANTATION OF MUCOUS MEMBRANE.—Professor Wölfler has pointed out the value of transplantations of mucous membrane. He said that where cicatrices were produced in cylindrical organs of the body, which were lined with mucous membrane, an operation could only be useful, if it were possible, after excision of the scar, to unite the mucosa. But that was impossible in many cases. Therefore he had employed the method of Thiersch (the transplantation of portions of epidermis) with great success. After having excised the thickened and indurated tissue from impermeable urethral strictures, he transplanted mucous membrane from a prolapsed uterus. The operation was completely successful. In the same manner he transplanted mucous membrane from a prolapsed rectum on to the conjunctiva in a case of blepharoplasty. He succeeded even in transplanting mucous membrane from frogs, pigeons, and rabbits with good results.

PEPPERMINT-WATER IN PRURITUS PUDENDI.—Dr. Routh writes to *The Lancet* that he has found peppermint-water very useful in the treatment of pudendal pruritus, especially those of the neurotic type. The remedy is to be employed as a lotion. The British Pharmacopœia preparation of aq. menth. pip. answers well, but is bulky for carrying about, and is incapable of concentration unless rendered alkaline. This is best done by borax, as being in itself soothing and antiseptic. Patients can easily make their own lotion, as required for use, by putting a teaspoonful of borax into a pint bottle of hot water, and adding to it five drops of ol. menth. pip., and shaking well, the parts affected to be freely bathed with a soft sponge. If no cracks or sores are present, this lotion will remove the itching; but if there be eczema, etc., or rawness from scratching, it is inapplicable, olive-oil, with five grains of iodoform to the ounce, being then more useful. The greatest and most permanent relief is afforded in the neurosal form, especially in the reflex pruritus which often accompanies pregnancy, and which then may take the place of reflex sickness or vomiting. It is also very useful in the pruritus which occurs in the climacteric, or in elderly women, in whom it may be only part of a general pruritus, and also in those cases of women of all ages where the urine simultaneously becomes of a very low specific gravity, without any evidence of having a gouty or granular kidney as a remote cause. In pruritus due to pediculi, ascarides, an irritable urethral caruncle, an endocervical polypus, early cancer of the cervix, distention of Bartholini's ducts or glands, the leucorrhœa of vaginitis, endocervicitis, and metritis, or the irritating discharges of advanced carcinoma uteri, or to a gouty or diabetic diathesis, the drug excels all others, cocaine inclusive, in affording relief, while endeavors are being made to remove the cause.

TETANUS SUCCESSFULLY TREATED WITH STROPHANTHUS.—Mr. W. J. Clapp reports, in *The Lancet* of July 21, 1888, a case of tetanus occurring in a man aged twenty-three. He was suffering from severe burning pains between the shoulders, extending down the spine. Abdomen rigid; spasms of body, chest, arms, thighs, and legs; jaws locked; countenance anxious; face and mouth contracted; pulse quick and wiry; temperature 108° F. He was in appearance a well-developed man; height, five feet and eight inches. He stated that about three weeks previously he had the nail of the little finger of the left hand torn when at work, from which he suffered severe pain, and believes that it was frost-bitten while following his employment (the cause of his illness). As the patient was constipated the writer gave him a purgative powder, which he had great difficulty in taking on account of the locked state of his jaw. He also prescribed a mixture containing large doses of bromide of potash and hyoscyamus, to be taken every hour for some days; and ordered liniments and poultices to be applied to the spine, abdomen, legs, and feet. The urine was dark and scanty, without any deposit. Beef-tea, mutton broth, milk-and-water, and lemonade were given often, as only very small quantities could be taken at a time. No improvement taking place, it was determined to give strophanthus a trial, and for this purpose Mr. Clapp employed tabloids containing two minims in each; one was given every three hours, it being with difficulty placed in his mouth, and cold water was taken after each tabloid. About the second day after commencing the strophanthus a decided improvement was noted. The writer could open the patient's mouth sufficiently to introduce the mouth of a feeding-cup. The spasms of the body, abdomen, and extremities became less frequent, the pulse quiet, and the temperature lower. He then continued the tabloids, gave another aperient, and ordered him, in addition to the beef-tea, broth, etc., corn-flour, custards, bread-and-milk, and bread and-butter, which he commenced to take regularly, and which he had not been able to do for some considerable time previously. The urine was copious and clear. All the symptoms gradually became less. The strophanthus was now given only twice a day, and was soon discontinued. In a fortnight afterward the man was able to walk and to take his usual food, the jaws being competent to perform their wonted work.

INHERITED DEFICIENCY OF A TOOTH.—Dr. Cryer says that he has, among his patients, members of the same family, representing five generations, each lacking the left lower lateral incisor tooth. An interesting feature of this remarkable instance of heredity is that one of the members of the same family has a supernumerary lower incisor.—*Philadelphia Medical Times*.

THE MEDICAL RECORD:

New York, August 25, 1888.

THE RADICAL TREATMENT OF HERNIA.

AMONG the many surgical procedures which have felt the impulse given to all capital operations by the adoption and gradual perfection of antiseptic methods, that of the permanent cure of hernia is not the least. The attempt to effectually close the opening through which the bowel protrudes is not new, and many and ingenious were the methods which were advanced by the older surgeons to compass this end. The "golden suture" the "royal suture," the actual cautery, instrumental invagination, and a host of other methods are now remembered only by historical writers; yet the subject of the radical cure of hernia occupies to-day a prominent position in medical literature, and is engaging the attention of many of the foremost surgeons of all countries. At the annual meeting of the British Medical Association, in Dublin, and also at that of the French Surgical Society, in Paris, this was one of the chief subjects for discussion. There were many speakers, and the number of cases upon which their conclusions were based was large, and it may therefore not be uninteresting to notice briefly some of the methods employed, as we find them collected by Mr. Keetley in a review of the discussions published in the July issue of the *Annals of Surgery.*

The first method is that employed by Mr. Mitchell Banks. He makes no claim to originality in the operation, which is the type of the procedures now in general favor, although surgeons frequently refer to it as "Banks' operation." In the case of inguinal hernia he dissects out the sac, opens it, replaces the bowel, and ties and cuts away all adherent omentum. The sac is then pulled down, ligatured high up, and removed, and finally the pillars of the ring are drawn together by silver sutures. In femoral hernia the sac is dissected away and removed, but no attempt is made to close the femoral opening.

Professor Macewen does not remove the sac, but forms it into a pad, which is returned through the canal and placed on the abdominal aspect of the internal ring. He endeavors to carry the conjoint tendon outward toward Poupart's ligament, and to unite with the transversalis and internal oblique muscles; for when the conjoint tendon is approximated to the outer pillar of the external ring the abdominal wall is thinned, and the natural valve, which the canal forms, is to a great extent obliterated.

Mr. Thornley Stoker employs a method which is substantially that of Dr. C. B. Ball. He opposes the use of silver wire and regards the drawing together of the walls of the canal by any form of suture as a matter of slight importance. The sac is first thoroughly isolated up to the internal ring, and the peritoneum is separated from its attachments for a little distance from that opening. Then the neck of the sac, which must be empty, is seized with broad-catch forceps and twisted through four or five complete revolutions, until it is felt to be quite tight, and then a catgut ligature is tied around the sac as high up as possible. "Two sutures of strong aseptic silk are now passed through the skin at a distance of about an inch from the outer margin of the wound, through the outer pillar of the ring, through the twisted sac in front of the catgut suture, and then through the inner pillar of the ring and skin upon the inside. These sutures prevent the sac from untwisting, and it is now cut off in front of them. A catgut drain is brought out of a separate opening at the back of the scrotum, and the two sutures are closed over lead plates, which lie at right angles to the wound."

Mr. Arthur Barker clears the neck of the sac around at the level of the external ring, and ligatures it after opening it to see that it is empty. It is then divided half an inch below the ligature, the scrotal part being left to take care of itself. "One of the threads hanging from the stump of the neck of the sac is now threaded in a Liston needle, and the latter is passed up the inguinal canal in front of the vas, guided by the left index-finger, which pushes the stump of the sac before it and feels for the inner aspect of the abdominal opening, that is, the internal ring. Here the needle is forced through one border of the ring and out through the external oblique muscle. It is then unthreaded and withdrawn, and is again filled with the other thread hanging from the stump of the sac. This is now carried in the same way as the first up the inguinal canal through the border of the opening opposite to that in which its fellow already lies, and through the external oblique as before. Both threads being now pulled upon, the stump of the sac is drawn well within the abdomen, and when the threads are knotted securely the first step, namely, that of closing the internal ring, is complete." Finally, the walls of the canal are approximated by from four to seven silk sutures.

Mr. Kendal Franks seeks to secure the ligatured stump of the sac between the pillars of the internal ring by means of a silver-wire suture. Some of his best results were obtained, he says, in cases in which the sac and its contents had slipped back into the abdomen, where he left them, merely closing the rings and the canal.

Mr. Keetley spoke in favor of injections into the canal, and reported the results of this method. Of eleven herniæ thus operated upon, five were cured, four were apparently not benefited, although they thought themselves better, and the others had been lost sight of. He believed the operation by injection to be far the safest and easiest of performance, though he thought it could not compare in its results with operations involving mechanical interference with the sac and canal. The latter, however, was not an operation to be lightly undertaken, and was safe in the hands of only a few experienced and careful operators.

The discussion at the French Surgical Congress was opened by M. Socin, who was most enthusiastic in his appreciation of the radical operation. He advocates complete removal of the sac, but thinks that approximation of the pillars by suture is seldom required. The operations, he thinks, in no sense dangerous, except in the case of the aged, or when the hernia is very large and the integument ulcerating, or when it is necessary to remove a large part of the omentum.

M. Léonté drags down the sac until its abdominal orifice is visible. Just above this point he divides the peritoneum by a circular incision, and the serous edges become wrinkled, thus tending to close the internal aperture. The internal ring is drawn together by a circular suture, and the interior of the sac is scraped with a sharp spoon, or irritated with chloride of zinc or carbolic acid. A silver-wire or silk suture is then passed through the integument and the sac.

M. Lucas-Championnière advocates the complete removal of the sac at a point as high up as possible, and insists upon the most thorough attention to every antiseptic detail.

These are by no means the only methods in use, for each surgeon seems to have devised a system of his own or to have modified that of another, so that the operations may be said to be almost as numerous as the operators. In skilled hands these operative "cases" of hernia are doubtless for the most part both effective and safe. But we think, with Mr. Keetley, that, in the hands of any but the experienced, the method of injections is by far the more safe, and is to be preferred even though the proportion of permanent cures resulting therefrom is somewhat less.

TREPHINING THE SPINE FOR THE RELIEF OF POTT'S PARAPLEGIA.

Trepanation or resection of the spinal column for the relief of paralysis following injury has been performed a number of times during the present century (Ashhurst has collected the reports of forty-three such operations), but we believe the following is the first recorded instance of trephining for the so-called pressure-paralysis of spinal caries. The case is reported by Mr. J. H. Thompson, in *The Lancet* of July 14, 1888.

A boy, aged seven, was admitted to the Hospital for Sick Children, Manchester, suffering from angular curvature of the spine. The disease, which had been first noticed about seven months before the admission of the patient, involved the mid-dorsal region. There was paresis of the lower limbs, with apparent psoas contraction and wasting of the muscles on the right side. In spite of the usual methods of treatment—absolute recumbency, the administration of hydrargyrum cum creta, and of iodide of potassium (the latter in gradually increasing doses up to fifty grains three times daily), and the application of the actual cautery, all of which were given a fair and prolonged trial—this condition gradually grew worse, until there was complete paralysis of both lower extremities, with loss of sensation and incontinence of urine and fæces. It was then decided to open the spinal canal, in order, if possible, to relieve pressure.

The operation was performed by Mr. G. A. Wright. An incision about four inches in length was made along the lines of the most prominent spinous processes, and the soft parts on each side separated so as to expose the osseous surfaces. Three laminæ were divided on each side, and were removed with their attached spines, uncovering the theca of the spinal cord, which, at the lower part exposed, was found surrounded by a buff-colored, tough, leathery substance; this was cut away with scissors. The cord did not appear to pulsate, but no point of constriction could be found. The muscles were brought together by deep sutures of catgut, and the skin with waxed silk; a small drainage-tube was left in. The wound, having been dusted with iodoform and boracic acid in equal parts, was dressed with sublimated wood-wool wadding. Careful antiseptic precautions were observed before and during the operation. The trunk was supported by a special iron splint.

The wound healed rapidly by first intention, except at the drainage opening, which, however, also quickly closed. No change was noticed until the twelfth day, when pin pricks could be felt about three inches below Poupart's ligament on each side. Nine days later there was slight voluntary flexion of the left thigh, and on the following day distinct voluntary contractions of the right quadriceps extensor were observed. Three days later pin pricks could be felt as far as the knees, and both thighs could be slightly flexed. On the day following this pin pricks could be felt in the left foot, but on the right side there was no return of sensation below the knee. No further improvement took place, the condition of the patient remaining *in statu quo* until March 17th (fifty-one days after the operation), when the area of anæsthesia was found to be increased, and a few days later was practically the same as before the operation; about the same time he lost all power of voluntary movement in the lower limbs.

This case, as the reporter remarks, demonstrates the possibility of safely exposing the spinal theca, but we cannot agree with him that it appears to justify the hope that operative procedure may give permanent relief in similar cases. In the forty-three cases above referred to, in which resection of the spine was performed for injury, relief was obtained in only four, or 9.3 per cent.; and there is no recorded instance, according to Ashhurst, of complete recovery after spinal resection. In Mr. Wright's case the relief was only temporary, the child being in the same condition two months after the operation as he was before it was attempted. The case is interesting, we fear, rather as showing the inutility, and therefore the unjustifiability, of operation in such cases, than as offering any hope of the permanent relief of Pott's paraplegia by spinal trepanation.

A PRACTICAL EXPERIMENT AND ITS RESULTS.

We referred some time ago to a communication made by M. Ossian-Bonnet before the Paris Academy of Medicine upon the use of antipyrine in sea-sickness. He had made use of the drug in an extended series of cases during a sea-voyage to South America and return, and felt himself justified, from the results obtained, in regarding antipyrine as curative of naupathia. The pretty safe prediction which we made at the time, that the drug would fail to relieve sea-sickness in many cases, has been verified in an amusing way.

There was a medical meeting held recently at Oran, and about one hundred and twenty physicians set sail from Marseilles to attend it. One of their number, M. Rollet, having recently listened to M. Bonnet's eloquent advocacy of antipyrine in sea-sickness, bethought himself that here was an excellent opportunity to put the question to a practical test. Accordingly he had prepared a number of packages of antipyrine powders, one of which, with an abstract of the discussion on sea-sickness before the Academy, and printed directions for the use of the remedy, he gave to each of his one hundred and nineteen *compagnons de voyage*.

As the ship sailed out of the harbor, all were on deck, discussing the subject of naupathia, and filled with the zeal of true scientific experimenters. Soon, however, the vessel began to pitch, and at the same time the discussion began to grow more languid, and one by one the pale and unhappy scientists went below to begin their experimentation. The pitching meanwhile became worse and worse, and presently the cabin was deserted, each experimenter seeking the seclusion of his stateroom in order the more quietly to swallow his antipyrine. At six o'clock dinner was announced, and fifteen appeared at the table. But their zeal was greater than their appetite, and all but four quickly returned to their experimentation, after ridding themselves of what little food they had unwisely swallowed.

On the return voyage the experiment was repeated, with nearly the same results. One hundred and twenty French physicians may now be relied upon to deny vehemently, and sadly withal, that antipyrine will cure sea-sickness.

News of the Week.

THE YELLOW FEVER AT JACKSONVILLE.—Within the past few days the fever cases in Jacksonville have increased in number. They are, however, mild in character, and the disease is under control. There does not appear to be any danger of its spreading beyond its present limits. The people in the infected and exposed places are in perfect accord with the health authorities in maintaining strict quarantine.

DR. W. BALLS-HEADLEY, of Melbourne, Australia, has been appointed lecturer on obstetrics and diseases of women at the Melbourne Medical University.

NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.—During the winter session of 1887–1888 over three hundred and thirty-five different physicians attended the courses of instruction of the New York Post-graduate Medical School and Hospital, 226 East Twentieth Street, New York City—an increase of more than sixty per cent. over last year. In the Hospital Department about four hundred operations were performed, all of major importance. To all of these matriculates had access, as the hospital is used solely as a means of clinical instruction. This remarkable increase in the matriculation list has necessitated both larger clinical space and hospital accommodations, so that a new clinical amphitheatre has been erected and will be used for the first time at the opening of the winter session, September 17, 1888. A new and commodious laboratory has been erected and furnished with the latest apparatus for the study of normal and pathological tissues. The nose-and-throat clinical room has also been enlarged. Professors Abraham Jacobi, Robert F. Weir, Joseph E. Winters, L. Bolton Bangs, and Peter A. Callan have been appointed to the Faculty. The session of 1888–1889 promises to be the most prosperous ever held.

THE ASSOCIATION OF POLISH PHYSICIANS AND NATURALISTS held its fifth annual meeting in Lemberg, July 18 to 22. There was an unusually large attendance, some five hundred delegates being present.

A QUEER FUNCTION FOR A BOARD OF HEALTH.—It is reported in the religious papers that idolatry is resuming its sway among the natives of the Sandwich Islands, and that Christianity is being rapidly crushed out. The *Congregationalist* says "that since 1880 there has been a systematic effort to reinstate old heathen practices, some of them unspeakably revolting in character, and the corrupt Legislature of 1886 actually organized a board of heathen sorcery, though under the innocent title of a board of health." The Hawaiian Board of Health, to judge from its reports, at least, seems to be doing good work, and we think our esteemed contemporary's fears have been somewhat unduly excited.

A SIBERIAN UNIVERSITY.—The Russian Government has established a university in Tomsk, Siberia, and proposes to add to it a medical department during the coming year.

HOW SHALL WE DRINK OUR BEER?—This weighty question has at last been settled by a German experimenter, who has written a book on the subject. If we fill an ordinary glass with beer, he says, and set it on the window-sill exposed to the sunlight, and put alongside of it a covered earthen mug filled with good Münchner beer, in a very few minutes the liquid in the glass will be found to have a bad smell and taste, while that in the mug will preserve its bouquet unchanged. Thus it is proven that sunlight is bad for beer, and that the "stein" is the proper vessel from which to drink the beverage.

SULPHUROUS-ACID FUMIGATIONS IN WHOOPING COUGH.—Pertussis is not usually regarded as a curable disease, although, as is the case with most affections of this class, remedies are often brought forward with the indorsement of being positively curative. Dr. F. E. Manby relates his experience in *The Practitioner* for August, 1888, with sulphurous acid, according to Mobin's method, which has given him great satisfaction. The method is the follow-

occur. The lacteal secretion of [illegible]

s not capable of carrying the infection, but only that oming from a tuberculous gland.

M. BAILLET strongly deprecated the

EXAGGERATIONS OF THE CONTAGIONISTS,

nd did not believe in the wholesale destruction of the heat from tuberculous animals. If an animal was fat nd in good condition, the flesh could be eaten with imunity even though there were tubercular deposits in the ngs, the pleura, and certain lymphatic glands. It was. f course, proper and necessary to reject any organs hich were found to be infected. and also the flesh in oximity to them, but the other parts of the animal ould be eaten. If an animal was greatly emaciated d was suffering from a generalized tuberculosis then it ould be wholly destroyed and no portion of it should

thusiastic in his appreciation of this method that he thinks a general application of it for six months would suffice to practically exterminate the disease.

THE PRIZE OF THE CAUCASIAN MEDICAL SOCIETY for the best paper read during the year has been awarded to Dr. Kucharski. His essay was upon the micro-organism of trachoma.

THE SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.—The following is the announcement of papers to be read at the annual meeting of the Southern Surgical and Gynecological Association, which will be held in Birmingham, Ala., September 11, 12, and 13, 1888: The President's Annual Address, W. D. Haggard, M.D., Nashville, Tenn.; The Annual Oration, W. F. Hyer, M.D., Holly Springs, Miss.; "Floating Kidney, with Vicarious Menstruation," DeS. Ford, M.D., Augusta, Ga.; "Gastrostomy," W. B. Rogers, M.D., Memphis, Tenn.; "The Medical Treatment of Fibroid Tumors of the Uterus," Bedford Brown, M.D., Alexandria, Va.; "Indications for Operative Interference in Cerebral Troubles," T. O. Summers, M.D., Jacksonville, Fla.; "A Case of Tubal Pregnancy, presenting Interesting Medico-legal Relations," E. P. Sale, M.D., Aberdeen, Miss.; "Superinvolution of the Uterus following Trachelorrhaphy," Virgil O. Hardon, M.D., Atlanta, Ga.; (*a*) "Dermoid Cysts of the Coccygeal Region," and (*b*) "Electrolysis in Gynecology and Surgery," E. J. Beall, M.D., Fort Worth, Tex.; "Alexander's Operation," W. L. Nichol, M.D., Nashville, Tenn.; "Hysterectomy in Cancer of the Uterus," W. H. Wathen, M.D., Louisville, Ky.; "The Extravagances and Impracticable Requirements of Modern Antiseptic Surgery, so far as the Country Practitioner is Concerned," J. M. Taylor, M.D., Corinth, Miss.; "Treatment of Fractures with Plaster of Paris Splints," W. F. Westmoreland, Jr., M.D., Atlanta, Ga.; "The Present Status of Electro-therapeutics in Gynecology," J. R. Buist, M.D., Nashville, Tenn.; "Antiseptics in Surgery and Gynecology," F. T. Meriwether, M.D., Asheville, N. C.; "The Attitude of Removal of the Uterine Appendages for the Cure of the Convulsive Neuroses," W. Locke Chew, M.D., Birmingham, Ala.; "Interesting Cases of Surgery," R. M. Cunningham, M.D., Pratt Mines, Ala.; "My Antiseptic Bags, or Practical Aseptic Surgery," J. W. Long, M.D., Randleman, N. C.; "The New Departure in Uterine Therapeutics—the Dry Method," T. A. Means, M.D., Montgomery, Ala.; "A Study of the Various Methods of Treatment of Laceration of the Perineum and Rectocele, with Report of Cases," J. H. Blanks, M.D., Meridian, Miss.; "Re-paresis of the lower limbs, with apparent psoas contraction and wasting of the muscles on the right side. In spite of the usual methods of treatment—absolute recumbency, the administration of hydrargyrum cum creta, and of iodide of potassium (the latter in gradually increasing doses up to fifty grains three times daily), and the application of the actual cautery, all of which were given a fair and prolonged trial—this condition gradually grew worse, until there was complete paralysis of both lower extremities, with loss of sensation and incontinence of urine and fæces. It was then decided to open the spinal canal, in order, if possible, to relieve pressure.

The operation was performed by Mr. G. A. Wright. An incision about four inches in length was made along the lines of [illegible] greatly disturbed for some weeks by reason of an unusual amount of sickness, which they attributed to witchcraft. Finally, suspicion centred upon one man, who was seized and searched, and in his pocket was found what is known among these people as a "conjuror's jack." It was a red flannel bag, one and one-half inch long and half an inch wide, containing ten No. 4 gunshot and one buckshot, all securely wrapped in a piece of red flannel. To one end of the bag was attached a piece of black thread, about ten inches in length. Since the charm has been destroyed the sick are recovering rapidly from their illness. The alleged sorcerer has fled from the town in order to escape death at the hands of his excited fellow-citizens.

DR. JOHANN DLAUHY, formerly professor of State medicine in the University of Vienna, died in that city on July 29th, at the age of eighty-one years.

MATERNAL IMPRESSIONS AND THE SEX OF THE FŒTUS.—A writer in a French journal offers the suggestion that the sex of a child is determined by the desire or the strong belief of the mother. Malformations, he says, are often the result of maternal impressions, and why should not the mental processes of the mother be equally potent in determining the sex of the fœtus?

THE SUICIDE OF DR. RIDLEY.—The coroner's jury in the case of Dr. James Ridley, late medical officer of Tullamore Jail, rendered a verdict, on August 17th, that Dr. Ridley committed suicide while suffering from temporary insanity, produced by apprehension of disclosures with reference to the treatment of the late John Mandeville in Tullamore Jail.

THREE HALE OLD PHYSICIANS.—Three of the oldest physicians belonging to any one family in the world are the brothers Ranson. Secretary Ranson, of Des Moines, is in his ninety-third year. Bass Ranson, of Findlay, O., is in his eighty-ninth year, and L. Q. Ranson, of Fremont, O., is eighty-four years of age. They are all well preserved and still follow their professions.

ABSENCE OF THE MUSCULO-CUTANEOUS NERVE IN MAN.—A case of this rare anomaly is reported by MM. Daraignez and Labougle in the *Journal de Médecine de Bordeaux*, August 5, 1888. The missing nerve was supplied by the external branch of the median. The two roots of this nerve, instead of uniting in the axilla, diverged, the internal one following the normal course of the nerve along the brachial artery, the external sending filaments to the biceps and brachialis anticus, and uniting finally with the other branch just above the elbow-joint. It here gave off sensory filaments to the skin and external portions of the arm and forearm.

DR. J. FIEUZAL died in Paris on July 28th, at the age of fifty-two years. Dr. Fieuzal was well known by his writings on ophthalmological subjects, a study which he took up in his later years and followed with ardor. He was a chevalier of the Legion of Honor, and was connected editorially with *La Tribune Médicale*. He was placed by Gambetta at the head of the Hôpital des Quinze-Vingts, where he displayed administrative abilities above the average.

HELLEBOREIN has been found by Drs. Venturini and Gasparini to be capable of exerting marked local anæsthetic effects when placed upon the cornea. It also produces local anæsthesia when injected into the tissues.

Society Reports.

CONGRESS FOR THE STUDY OF TUBERCULOSIS.

Held in Paris, July 25, 26, 27, 28, 30, *and* 31, 1888.

(Special Report for The Medical Record.)

Wednesday, July 25th—First Day.

The opening session of the Congress was devoted to the business of organization and the election of officers. The following were the officers elected: *President*, M. Chauveau; *Vice-Presidents*, MM. Villemin and Verneuil; *Secretaries*, MM. Cany, Gallois, Piot, and Thounet. Honorary Presidents from the United States, Brazil, and most of the countries of Europe were also elected.

M. Chauveau, the newly elected President of the Congress, then delivered the

OPENING ADDRESS,

in which he reviewed the advances made in the study of tuberculosis in modern times, referring especially to Villemin's views, which had been so strikingly confirmed by Koch's discovery. He then outlined the work to be done by the members of the Congress, and expressed the hope that the results of this work would be such as would mark an era in the history of tuberculosis.

M. Verneuil followed with a short address in which he referred to the

SCIENTIFIC CO-OPERATION OF PHYSICIANS AND VETERINARIANS,

as exemplified in this meeting, and hoped that it would be but the beginning of a series of works in which the two professions would be united in doing battle to a number of diseases common to man and the lower animals.

M. Cornil opened the scientific work of the Congress with a communication on

TUBERCULOSIS OF THE MUCOUS SURFACES.

One of the most important facts which have been proven by experiment is that the tubercle bacillus may penetrate the unbroken mucous membrane. This had been shown in the case of the lungs and of the intestinal tract. The author had made a special study of

TUBERCULAR AFFECTIONS OF THE UTERUS.

In most cases tuberculosis of the genital organs begins in the tubes, and the uterus is secondarily infected by the caseous matter descending into its cavity from the diseased tube. He had seen one case of the disease affecting the cervix alone, in a woman who had no pulmonary or peritoneal trouble, in which it seemed probable that infection had occurred during coitus. In connection with M. Dobroklonsky he had made a number of experiments by introducing a few drops of a culture-fluid containing the specific micro-organisms into the vagina of female guinea-pigs, and had found, on later examination, that the uterus was tuberculous. This showed that it was certainly possible to infect this organ through the vagina.

M. Nocard read a paper on

THE DANGERS FROM THE USE OF THE FLESH AND MILK OF TUBERCULOUS ANIMALS.

It was incorrect, he said, to assume that the flesh of tuberculous animals was always capable of exciting the disease in those who ate it. That there was some danger in eating such meat he admitted; but he thought the danger very slight. It was wise to guard against all means of infection, but it was also necessary to proceed with caution, for immense interests were concerned in raising cattle and in preparing food for the market, and it was not just to injure these interests and to enormously increase the cost of meat by precipitate action without reflection. In regard to milk, the question was somewhat different.

ALL COWS' MILK SHOULD BE BOILED

before being given to infants. It was the general opinion of those most competent to judge, that the milk is infected only when the tubercular process has invaded the glandular tissue. But in view of the great difficulty of recognizing mammary tuberculosis in cows, it was safe to look upon all raw milk with suspicion, and to allow infants to drink it only after it had been rendered innocuous by boiling. With goats' milk, however, no such precaution was necessary, for a tuberculous goat was one of the rarest of curiosities.

Thursday, July 26th—Second Day.

The question proposed for discussion at this session was the following:

THE DANGERS RESIDING IN THE USE OF THE FLESH AND MILK OF TUBERCULOUS ANIMALS, AND THE MEANS OF PREVENTING THEM.

M. Arloing opened the discussion with a paper advocating

THE FORCIBLE SEIZURE OF TUBERCULOUS ANIMALS.

The first thing necessary was to proclaim tuberculosis in animals a contagious disease, thus, under the law of 1881, placing the disposal of all such diseased cattle in the charge of a commission. He did not agree with M. Nocard that the danger of infection through the flesh of tuberculous animals was slight. It was true that the bacilli did not long preserve their virulence in muscular tissue; but it was fair to suppose that a certain number existed in the flesh at the time the animal was killed, and they would then retain their vitality in the dead meat, and be capable of infecting those who ate of it. The temperature to which beef was ordinarily exposed in the process of cooking had been shown to be insufficient to destroy the bacilli. Experiments made by feeding diseased meat to guinea-pigs showed that twenty per cent. of the animals became tuberculous, and, therefore, of twenty diseased beeves, four might be assumed to be capable of spreading tuberculosis by their flesh.

M. Bang, of Copenhagen, read a communication on

TUBERCULOSIS OF THE MAMMA IN COWS,

and its relation to diseased milk. He did not believe that the early diagnosis of this condition was as difficult as was commonly supposed. One of the earliest symptoms is a tumefaction in the gland, which may exist a long time before any changes are observed in the milk. It is only when induration follows upon this swelling that the milk becomes of a yellowish color and contains fibrinous flocculi. The lacteal secretion of all tuberculous cows is not capable of carrying the infection, but only that coming from a tuberculous gland.

M. Baillet strongly deprecated the

EXAGGERATIONS OF THE CONTAGIONISTS,

and did not believe in the wholesale destruction of the meat from tuberculous animals. If an animal was fat and in good condition, the flesh could be eaten with impunity even though there were tubercular deposits in the lungs, the pleura, and certain lymphatic glands. It was, of course, proper and necessary to reject any organs which were found to be infected, and also the flesh in proximity to them, but the other parts of the animal could be eaten. If an animal was greatly emaciated and was suffering from a generalized tuberculosis then it should be wholly destroyed and no portion of it should be allowed to be sold or eaten.

M. Butel thought that, in a matter of such vital importance to the well-being of the community, no considerations of a commercial nature should be allowed to bias the judgment of the speakers. He believed that the risk of infection from diseased meat was too great to allow of any compromises or fine distinctions.

ALL MEAT FROM TUBERCULOUS ANIMALS SHOULD BE SEIZED,

but it was only just that the government should indemnify the owners of the sacrificed cattle for their loss. To show the inefficacy of the present regulations concerning the inspection of meat, it was only necessary to mention the fact that in Paris, of 260,000 cattle slaughtered during the year 1883, only eleven had been condemned as unfit for food. He believed that a large proportion of sufferers from phthisis acquired the disease through the ingestion of infected meat.

M. **Grissonnanche** read a paper on

THE EARLY DIAGNOSIS OF PULMONARY TUBERCULOSIS IN CATTLE.

His experience as a veterinary surgeon, practising in the country, had led him to regard the early diagnosis of phthisis in cattle as a much more easy matter than that of glanders. Pulmonary tuberculosis is characterized from the first by tumefaction of the retropharyngeal glands; the inspiratory movements are irregular; a harsh friction-sound is heard on auscultation, resembling somewhat the sound produced by rubbing the thumb over a tambourine. The cough is short and not easily provoked except by sharp percussion on the thoracic parietes, a procedure which evidently causes pain to the animal. The disease is met with most frequently in cattle living together in herds, hence the necessity of its prompt recognition, and of the isolation of the affected animal.

M. **Veyssière** opposed strongly the views set forth by M. Baillet, and hoped that the Congress would not endorse them. He thought the distinctions made between localized and generalized infection were too fine to be followed by the ordinary meat inspector, and insisted upon the rejection of any infected animal, whatever its general appearance of health may be. He had seized a very fat and apparently well-conditioned cow on account of a local tuberculosis, and had injected some of the juice expressed from the meat into two rabbits. Both animals died, and an examination showed the presence of tubercular alterations in the lungs and liver.

M. **Moulé** referred to the danger of infection by eating the flesh of

TUBERCULOUS POULTRY,

a matter which seemed to have been overlooked in the discussion hitherto. His observations had led him to believe that domestic fowls were very frequently the subject of tuberculosis, the disease often involving the abdominal organs. Thus pâte-de-foie-gras was especially dangerous, being in some cases almost a pure culture of tubercle bacilli.

M. **Thierry** said that the inspection of meat in all the larger cities ought to be most vigorous; while in the country such precaution was less necessary, for the butchers there were generally good judges of cattle and rejected those that they considered unsound.

M. **Villain** said that the proportion of tuberculous animals brought to the abattoirs of Paris was about six in a thousand head.

Mr. Robinson, of Greenock, Scotland, said that from an experience of fourteen years as meat inspector, he had come to the conclusion that

TUBERCULOSIS IN ANIMALS IS COMPARATIVELY RARE,

but that when it does exist, even in cases in which it seems to be most limited, a more careful examination will generally show the presence of glandular involvement. He urged upon the Congress to pass some very strong resolutions against the use of the flesh of diseased cattle, for he did not think it possible to decide safely, in the case of tuberculous animals, between those that were fit to be eaten and those that were not, and it was necessary therefore to exclude all.

M. **Guinard** called attention to the danger which existed in the practice of

DRINKING FRESH BLOOD

at the abattoirs. He had seen a lady drink the blood from a fine-looking animal which, however, was found afterward to be diseased and was condemned. This lady was already consumptive, but it was not uncommon for physicians to send patients with simple anæmia to the abattoirs, and for them the practice might be fraught with evil.

A RESOLUTION

was then proposed to the effect that, in the opinion of the Congress, all animals affected in any degree with tuberculosis should be seized and condemned as unfit for food. This resolution was carried with only three dissenting votes.

M. **Degive** made some brief remarks on

TUBERCULOSIS AND VACCINATION.

He said that it was the practice in Belgium to kill all the calves from which vaccine had been taken, and to reject the latter if the animal was found to be tuberculous.

The President said that this was certainly an excellent rule to follow, but one could easily exaggerate the dangers to be apprehended from this source. In the first place, it was only in very rare cases that the vaccine contained tubercle bacilli, and even then experiments had shown that it was very difficult to inoculate an animal with tuberculosis through a superficial abrasion of the skin. The advantages of vaccination were too great to be counterbalanced by the almost infinitesimal risk of acquiring tuberculosis by this means.

M. **Solles** then read a paper on

A NEW MICRO-ORGANISM FOUND IN THE LUNGS OF PHTHISICAL PATIENTS.

When this organism was introduced into the circulation of rabbits, the animals died with a disease very distinct from tuberculosis, but with constant and characteristic lesions. This microbe could also be propagated by cultures from the blood of consumptive patients. It was distinct from the tubercle bacillus of Koch, as was shown by the fact that it did not take up Ehrlich's stain.

M. **Lannelongue** presented a communication on

TUBERCULAR HEPATITIS.

He said that there were two forms of tuberculosis of the liver, excluding miliary tuberculosis, viz., a tubercular infiltration or caseous hepatitis, and cavernous ulceration or tubercular abscess of the liver.

M. **La Torre** read a paper on

HEREDITARY TUBERCULOSIS.

He had come to the conclusion, from his observations and from the study of all attainable statistics, that the influence of a tuberculous father is more marked than that of the mother similarly affected. This was contrary to the generally received opinion.

Friday, July 27th—Third Day.

M. **De Brun**, of Beyrut, presented a communication on

THE ANTAGONISM BETWEEN MALARIAL FEVER AND TUBERCULOSIS.

The author said that he was struck on his first arrival in Syria with the fact that phthisis was much more rare there than in France. It could not be due to any advantages in the climate of the country, for the incessant rains of winter, the continued heat and moisture of the atmosphere in summer, and the depressing winds from the desert, all contributed to favor the spread of tuberculosis. The only explanation of the fact, therefore, that was at all satisfactory was furnished by the law of Boudin, who maintains that there exists an antagonism between malaria and tuberculosis. Tuberculosis was absolutely unknown in former times when there was no attention paid to sanitation, but its advent coincided in time with the introduction of drainage, and other works designed to prevent malaria. Just in proportion as these works were successful and as malaria diminished, phthisis increased. Often indeed, in malaria, there is pulmonary congestion, and this, taken in connection with the debility and lowered general vitality of those affected, not infrequently leads to a diagnosis of phthisis, but the effect of quinine in dispelling all these symptoms discloses quickly their true character.

M. Piot, of Cairo, related his experience with

TUBERCULOSIS IN EGYPT,

which, he said, had led him to conclusions similar to those of the preceding speaker.

M. Redard read a paper on

THE SURGICAL TREATMENT OF TUBERCULAR ARTHRITIS IN CHILDREN.

He was in favor of opening widely the diseased articulation with the thermo-cautery, scraping away all the affected parts, whether bone, cartilage, or synovial fringes, and providing for subsequent irrigation. Recurrence of the disease was frequent, but after two or three operations a definite cure resulted.

M. Verneuil said that he had abandoned long ago resections, and other operations made by rule, in children. He favored scraping away the diseased parts, but he was also in favor of previous sterilization of the tubercular centres with iodoform and ether. He had seen most excellent results from such measures.

M. Chantemesse presented a communication, embodying the results of a series of experiments made by M. Widal and himself, to determine the

PERSISTENCE OF TUBERCLE BACILLI IN RIVER WATER.

The authors had used the water of the Seine for this purpose, some being previously sterilized and some taken just as it flowed in the river. To various samples, some kept at a temperature of 45° to 50° F., and the rest at 60° to 70° F., pure cultures of tubercle bacilli were added, and it was found that the micro-organisms were still present at the end of seven weeks, but the injection of this water into the peritoneal cavity of guinea-pigs gave negative results.

M. Arloing reported the results of some experiments of MM. Galtier and Cadéac to determine the length of time during which the

VIRULENCE OF TUBERCLE BACILLI IN STAGNANT AND RUNNING WATER IS PRESERVED.

Pieces of tuberculous tissues were placed in the bottom of a flask in which was maintained a stream of running water of a temperature of about 60° F. It was found that the micro-organisms were still active at the end of six weeks. In stagnant water the virulence was preserved for seventeen or eighteen weeks.

M. Arloing then read a paper embodying the results of some experiments of his own in the way of

THE PREVENTION OF TUBERCULOSIS AFTER INOCULATION.

He inoculated a certain number of guinea-pigs under the skin of the thigh. Seven days later he removed the inguinal glands from two of the animals, although the glands appeared to be healthy. On the fifteenth day three of the remaining animals presented some swelling of the glands, which were thereupon removed. Two animals remained which were not operated upon. Two months and a half after the inoculations the seven animals were killed, and all presented marked lesions of general tuberculosis. Thus it would appear that exsection of the glands had no effect upon the course of the disease.

The author then related some further experiments made with a view of testing the efficacy of

PREVENTIVE INOCULATIONS OF TUBERCULOSIS.

It had been thought at one time that scrofulous glands contained the tubercular virus in an attenuated form. He had accordingly practised inoculations with scrofulous material, subsequently inoculating the animals with unmistakable tuberculous products. The result was that tuberculosis developed, seemingly uninfluenced in its course by the previous inoculations. Other experiments with the previous repeated inoculations of typhoid virus showed that the latter exercised no restraining influence upon the course of the tubercular disease.

M. Babès presented a communication on

THE BACTERIAL RELATIONS OF THE TUBERCLE BACILLUS.

He had noted the bacterial conditions in 73 autopsies made on children, 65 of whom had tuberculous glands, and had found Koch's bacillus in but 45. In 52 autopsies of cases of more general tuberculosis he had found the tubercle bacillus alone in but 10 instances. In all the other cases there were other microbes associated with it. These were most commonly the micro-organisms of suppuration, but in certain special diseases, tuberculous in character, such as pleurisy, peritonitis, meningitis, etc., the microbes present were those usually credited with the production of the ordinary non-tubercular forms of the same diseases. He concluded that

UNCOMPLICATED TUBERCULOSIS RARELY CAUSES DEATH,

at least in children, but it usually opens the door to other bacteria which induce the special and fatal forms of the disease. He believed also that latent, incapsulated tuberculosis, which is extremely frequent in children, under the form of scrofulous glands, may become active in the course of affections excited by other micro-organisms.

M. Duret then read a paper on

TUBERCULOSIS OF THE GLANDS.

He recognized three forms of the affection: 1. Fibro-caseoma; 2, simple caseo-tuberculosis; 3, suppurative caseo-tuberculosis. The treatment of the first form should consist in extirpation of the affected glands. In the second form the author advised igni-puncture and scraping out of the caseous material. In the third form, in which ulcers or fistulous tracts exist, his plan was to destroy the fungous granulations with the thermo-cautery.

M. Cornil presented a communication, on behalf of himself and M. Toupet, on

PSEUDO-TUBERCULOSIS.

The authors had examined a little tumor, the size of a pea, removed from the finger. It was composed of fibrous tissue, in the midst of which were certain small nodules, having all the appearances of tubercles, and containing within them perfectly characteristic giant cells. The degenerating cells, found around the giant cells in typical tubercles, were, however, absent in this case. Repeated careful examinations failed to reveal the presence of the bacilli of tuberculosis. Upon the strength of this and other similar tumors observed by the authors, they concluded that the presence of the pathological formation, known as tubercle, was not always an evidence of the disease tuberculosis, and that, therefore, it was not possible to rely with certainty upon the anatomical diagnosis, and the latter should always be supplemented by a bacteriological examination.

M. Hurean de Villeneuve read a paper on the use of

RAW MEAT AND BLOOD IN THE ALIMENTATION OF CONSUMPTIVES.

He thought that the exclusive use of these substances was bad for tuberculous patients. A more rational treatment consisted in the administration of strychnine and arsenious acid, which drugs, given in sufficient doses, tended to excite a good appetite. When the desire for food was once aroused the only indication was to satisfy the patient with an abundance of good nourishing food such as pleased his palate.

M. CARTIER sent a communication on the same subject. He recommended the flesh of the sheep or goat as most suitable to be eaten raw. If it was considered desirable for a patient to drink fresh blood, that coming from these same animals should be chosen by preference. The writer had himself drank sheep's blood, and said that, with his eyes shut, he would have supposed that he was drinking milk fresh from the cow. There was nothing in the least disagreeable in its taste.

Correspondence.

THE MNEMONICS OF ELECTRICAL TERMS.

To the Editor of The Medical Record.

SIR: Since electricity has assumed considerable importance in medicine, and as the general practitioner, burdened as he is with so many things, may find some difficulty at times in recalling to mind the definition of electrical terms, it may not be out of place to give to your readers an illustration that I have found useful in fixing the meaning of these terms. To the non-medical mind the formula might seem vulgar, but in science there is nothing unclean. The term *volt* is a common one in electricity. It means the unit of measure of electric force or power, or, we might say, pressure. Thus we say a battery giving so many volts is necessary to run an electric light or kill a dog.

We may represent the voltage by the contractile power of a male bladder.

The term *ohm* is the unit of measure of resistance to the passage of an electric current. The ohm or ohmage may be represented, then, by the calibre of the urethra attached to this bladder; or, a still better illustration to the medical mind, a stricture in that urethra (a not uncommon condition of the male urethra).

The term *ampère*, or milliampère (the latter meaning the thousandth of an ampère), is the unit of measure of the amount of electric current passing through an object in a second of time. It is a resultant of the pressure and resistance, the volts and ohms, and may be represented by the volume of urine passing the stricture. Thus the more powerful the bladder (more volts) and the less the stricture (fewer ohms) the greater the current (more ampères). This equation can be varied indefinitely. This illustration explains why the same number of cells will not give the same number of ampères or milliampères when passed through different persons or different parts of the body; the resistance is different.

The following, then, would be the graphic formula for this subject:

Volts or voltage = bladder.
Ohms = stricture.
Ampères = passing current.

There is no patent on this formula, and Professor Loisette is at liberty to use it in his method for strengthening the memory.

W. E. FOREST, M.D.

NEW YORK, August 9, 1888.

MIDDLE-EAR DISEASE AND POLITZERIZATION.

To the Editor of The Medical Record.

SIR: In your issue of August 11th, page 152, Dr. Frank W. Ring contributes an article entitled "Four Cases of Acute Inflammation of the Middle Ear from the Use of Roosa's Bulb Nasal Inhaler." I desire, in a kindly spirit, to take issue with Dr. Ring. I infer that in three of his four cases he resorted to Politzerization *after* having made applications to the nose and naso-pharynx. In the first case, he applied "iron and glycerine" solution to the "posterior wall of the pharynx" and a spray to "the throat and nose with Dobell's solution, and *finally* inflated her ears with the Politzer bag, using Roosa's pear-shaped cylinder bulb." In the second case, he "sprayed her nose with Dobell's solution . . . and inflated her ears with the Politzer bag, and Roosa's pyriform bulb." In the third case, he "used the Dobell spray . . . and inflated with the Politzer bag, using Roosa's bulb."

The doctor does not distinctly say that in the second and third cases the Politzerization *succeeded* the local applications, but as he definitely states the order of procedure in the first case, and mentions Politzerization last in the others, it is reasonable to suppose that the order of application was the same in all. If this be the case, I maintain that the inflation of the ears, after the throat-applications had been made, very probably forced some of the solution into the ears, and that this was the cause of the inflammation. It is, I believe, very generally admitted and urged by all authorities that the ears must not be inflated in any manner just after the naso-pharynx has been swabbed or sprayed. I resort to Politzerization, both with and without Roosa's bulb, constantly, that being always the first manipulation in such cases, and I have never seen any new trouble set up or any old trouble aggravated when the throat-applications *succeeded* the inflation.

Are we not warranted in the belief that in the first three of Dr. Ring's cases the sediment in his water-tank, the infusoria and bacteria, and the Roosa bulb can be eliminated as etiological factors?

Would not the reversal of the order of procedure have removed all danger?

His fourth case shows an inflammation following inflation alone; but it seems hardly fair to insist that Roosa's bulb is directly and solely responsible for this accident until a sufficient number of cases shall have been observed to eliminate the possibility of simple coincidence.

H. P. ALLEN, M.D.

COLUMBUS, O., August 14, 1888.

THE STORAGE OF LIFE.—At the last anniversary meeting of the Sanitary Institute of Great Britain, Dr. B. W. Richardson delivered an address, taking as his subject the "Storage of Life as a Sanitary Study." The conditions favoring the storage of life he dealt with under the headings of hereditary qualification, the virtue of continence, maintenance of balance of bodily functions, perfect temperance, and purity from implanted or acquired diseases. While urging the importance of maintaining the balance of the working organs of the body as a means of keeping up the storage of life, the lecturer spoke yet more emphatically upon what he termed "all-round temperance"—temperance in speech, action, thought, as well as in eating and drinking. Everything that quickened the action of the heart he regarded as a stimulant, taxing and reducing the storage of life. Necessarily the work of the sanitarian called for appreciative remark toward the close of the lecture, the prevention of "damaging diseases" promoting the storage of life. After all, in spite of the interest of the lecture, the moral is somewhat trite. The advantages of a favorable family history, the disadvantages of acquired diseases, the influence of personal habits of restraint—all these have long been granted. The individual may toil and strive, but he is still largely at the mercy of his neighbor, whose erratic proceedings may greatly upset all the foresight of storage. While all admit the value of personal attention to sanitary and physiological laws, most people will wish for greater powers of sanitary control over the actions of their neighbors.—*The Lancet.*

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 12 *to August* 18, 1888.

Sutherland, Charles, Colonel and Medical Director. Directed to inspect the Medical Department at Forts Brady, Mackinac, and Wayne, Mich.; Forts Porter, Niagara, and Ontario, N. Y.; Madison Barracks and Plattsburg Barracks, N. Y.; Fort Preble, Me.; Fort Warren, Mass.; Fort Adams, R. I.; Fort Trumbull, Conn. Paragraph 7, S. O. 168, Division of the Atlantic, August 16, 1888.

Janeway, John H., Major and Surgeon. Granted leave of absence for one month, on Surgeon's certificate of disability. Paragraph 2, S. O. 41, Division of the Pacific, August 8, 1888.

Brown, Harvey E., Major and Surgeon. Upon being relieved by Captain William C. Gorgas, Assistant Surgeon, to proceed to his proper station, Jackson Barracks, New Orleans, La., reporting in person to the Commanding Officer of that post for duty. Paragraph 8, S. O. 187, A. G. O., August 14, 1888.

Cowdrey, Stevens G., Captain and Assistant Surgeon. Granted leave of absence for one month. S. O. 77, Department of Texas, July 25, 1888.

Tarney, George H., Captain and Assistant Surgeon. To proceed to St. Augustine, Fla., via Palatka, accompany the U. S. Troops thereat to Huntsville, Ala., as Medical Officer, and thereafter return to his proper station (Fort Monroe, Va.). Paragraph 4, S. O. 165, Division of the Atlantic, August 13, 1888.

Appel, Daniel M., Captain and Assistant Surgeon. Ordered to Fort Bliss, Tex., for temporary duty. S. O. 77, Department of Texas, July 25, 1888.

Gorgas, William C., Captain and Assistant Surgeon. Leave of absence granted in S. O. 177, A. G. O., August 1, 1888, revoked, and ordered to proceed to Camp Monte Sano, Huntsville, Ala., and report in person to the Commanding Officer thereof for duty, relieving Major Harvey E. Brown, Surgeon. Paragraph 8, S. O. 187, A. G. O., August 14, 1888.

Wood, Leonard, Assistant Surgeon. To proceed from Fort McDowell to San Carlos, A. T., and carry out the instructions of the Department Commander. Upon completion of that duty to return to proper station. S. O. 89, Department of Arizona, August 1, 1888.

Official List of Changes in the Medical Corps of the United States Navy for the week ending August 18, 1888.

Ferebee, N. M., Surgeon. Detached from the Franklin, and ordered to the Naval Hospital, Norfolk, Va.

The Power of the Imagination.—Dr. Durand, wishing to test the practical effect of mind disease, gave a hundred patients a dose of sweetened water. Fifteen minutes after, entering apparently in great excitement, he announced that he had by mistake given a powerful emetic and preparations must be made accordingly. Eighty out of the hundred patients became thoroughly ill and exhibited the usual result of an emetic; twenty were unaffected. The curious part of it is, that with very few exceptions the eighty "emeticized" subjects were men, while the strong-minded few, who were not to be caught with chaff, were women.—*New Orleans Picayune.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 18, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	19	6
Scarlet fever	54	8
Cerebro-spinal meningitis	2	3
Measles	130	13
Diphtheria	89	39
Small-pox	1	0
Yellow fever	0	0
Cholera	0	0

Advanced Medical Views One Hundred Years Ago.—In 1784, Dr. John Gardiner, President of the Royal College of Physicians, and Fellow of the Royal Society of Edinburgh, wrote as follows: "Apart from imprudences of diet and living, human beings suffer most from the effects of cold and heat, from marsh miasm, but especially from human effluvia, or human infection and contagion, or the typhus poison, and sometimes from al combined. Cold and wet produce catarrhal and rheumatic affections, and catarrhs are, perhaps, often merely rheumatic affections of the mucous membranes. Catarrhs of all the mucous membranes are attended with acrid secretions like those which irritate and almost excoriate the nostrils and lips, and should be neutralized in the stomach, bowels, air-tubes, lungs, and perhaps kidneys. In every severe catarrh of the lungs there is more or less tendency to an obscure inflammation after the patient has got rid of his cough and seems to be perfectly recovered, and there frequently remains, in different parts of the substance of the lungs, small obstructions without any apparent inconvenience. A gradual resolution of these may take place, but they often increase in number and at last become irresolvable, and lay the foundation of what are called tubercles." He says: "This irritation of the mucous membranes, but especially the absorption of the acrid mucus, causes catarrhal fever which may become contagious, like the contagious catarrh known by the name of *influenza*, unless the air of the house be good, and the general condition of the city clean. If foul human effluvia, or the typhus poison, be added to catarrh, it becomes virulent and contagious." He says he also knows that consumption of the lungs may be brought on by a person lying on the same bed, in a badly ventilated house or hospital, with another suffering from phthisis pulmonalis, and that this acquired disease may terminate in open sores, abscesses, or ulcers of the lungs. He conceives that the lungs of the second sufferer are inoculated with the poison of the first. But Dr. Gardiner is especially concerned about catarrhs of the stomach and bowels, and the necessity of neutralizing or evacuating this acrid mucus before the gall-ducts and liver become involved and a serious bilious complication is added. Under the influence of spoiled mucus the bile may ferment and putrefy, and a bilious catarrhal fever may arise. Emetics of ipecac, aided by large quantities of warm water, with or without the addition of some alkali, like soda, or mild saline laxatives, like Rochelle salts, he thinks will prevent the absorption of acrid or spoiled mucus and bile, or the intervention of a mucous, or catarrhal, or bilious fever. Subsequently he used the mineral acids to constringe the mucous glands and membranes, of alum for the same purpose, followed by Peruvian bark and wine if the debility was great. He knew that bilious fevers were often produced by marsh and other miasms, but was sure that they could originate without this, from bad diet, and human effluvia in dirty houses and towns. "Marsh miasm," he says, "arises in the greatest quantity from fenny and marshy grounds, more or less impregnated with putrid exhalations from an immense quantity of corrupting vegetable and some animal substances, and aquatic plants, insects, and reptiles dying and corrupting, produce vapors of a more or less malignant nature." He is confident that a lesser degree of malaria must arise from every place where there is heat, moisture, and filth, even in towns and villages, especially unpaved ones. He thinks that marsh miasm is not so much inhaled as swallowed with marsh or other water, or it lodges in the mouth and throat and is swallowed down into the stomach; and advises exposed people to rinse their mouths frequently, especially before eating or drinking, not to swallow their saliva, but to chew calamus in preference to tobacco, and even to chew Peruvian bark. But he says the most active cause of fever in cities, towns, villages, and badly appointed houses, is human effluvia, or the typhus contagion, which is capable of making all other fevers most dangerous in kind, and adding to the malignity of all other co-operating causes. In camps human contagion arises chiefly from the privies; but is found to have still greater effects in crowded hospitals, jails, and ships, where it attains its highest degree of virulence from the excrementitious effluvia of those sick and dying of putrid distempers. He says it has been repeatedly observed that this malignant vapor becomes more contagious and powerful in its effects some time after it has been thrown off from the body, aided by excrementitious matters collected in the apartments of the sick, especially where it is imbibed by blankets and woollen cloths, or even cotton fabrics, which retain it for a considerable time; especially when they have been rolled up moist, and delay has happened in sending bed and body clothes to the wash. He says: "Just as marsh miasm may come from places which are not very marshy, so may human effluvial contagion come not only from jails and ships, but also in private houses where there is not a free circulation of air, and especially where there is a total neglect of cleanliness in their persons and rooms, which is so frequent an attendant of poverty. A smaller quantity of the same unwholesome human effluvia exists in every city, town, and village, and causes the principal difference between town and country air. And even when not great enough to cause typhus fever pure and simple, always adds to the severity and malignity of most other diseases." He says the marsh miasm is of a putrid nature, and human contagion, or the typhus poison, still more so, and both may add themselves to the specific causes with which all sick persons are afflicted. Marsh miasm may acquire a degree of noxious power equal to the human contagion or typhus poison of jails and ships, and then the two diseases seem nearly the same.

HIPPOCRATES ON METRIA, URÆMIA, PUERPERAL FEVER, PYÆMIA, SEPTICÆMIA, AND PERHAPS DIPHTHERIA, ETC.—*Case I.*—A maid was taken ill of fever, without thirst at any time. She had no relish for and loathed food, her alvine discharges were small, her urine thin, scanty, and dark colored. She had pain about the nates, which came to suppuration and burst on the sixth day, when she had a crisis without sweat, and became free of fever. On the seventh day she had a rigor, became slightly heated, and sweated. On the eighth day she had another rigor, followed by a slight one, and her extremities remained cold ever after. On the tenth day, after a sweat, she became delirious, but was afterward calm. She had an intermission of fever on the twelfth day, but soon talked much incoherently, and her bowels again became disordered with bilious, scanty, unmixed, thin, and acrid discharges, which required her to get up frequently. She died on the seventh day after the return of the delirium. In the beginning of her attack she had pain in her throat, which was red throughout, with thin, acrid, and copious defluxions. She coughed, but had no concocted sputa. She was silent, despondent, and had no hopes of herself. The affection of the throat was a common complication in this epidemic.

Case II.—A woman had a complaint with fever which commenced in her tongue and throat, which were red and parched. On the third day she had a rigor followed by an acute fever, and a reddish hard swelling on both sides of the neck and chest. Her extremities were cold and livid, her respiration was labored, and her drink returned by the nose. She could not swallow, and her alvine and urinary discharges were suppressed. On the fourth day all her symptoms were exacerbated, and on the sixth she died.

Case III.—A woman from a miscarriage was taken ill of fever, with dry tongue, thirst, nausea, insomnolency, and thin, copious, undigested dejections. On the second day she had a rigor followed by high fever, copious diarrhœa, and no sleep. On the third she was worse; on the fourth delirious, and her urine scanty and thin. On the seventh she died.

Case IV.—Another woman, after a miscarriage about the fifth month, was seized with fever, sometimes with stupor, at others with insomnolency, pain in the loins and head. On the second day she had scanty and thin discharges, which grew more copious and worse on the third. On the fourth she was delirious, with frights, despondency, strabismus of the right eye, a cold sweat about the head, and cold extremities. On the fifth was still worse, and talked incoherently, but afterward became calm. She had no thirst, was sleepless, had diarrhœa with copious and unseasonable dejections, and her urine was thin, scanty, and dark. On the fifth and sixth days her extremities were cold and livid, and on the seventh she died.

Case V.—A woman having brought forth a son, in a first and difficult labor, was seized with fever, thirst, nausea, and cardialgia; her tongue was dry; evacuations thin and scanty; and she had no sleep. On the second day she had a slight rigor, followed by high fever, and a faint cold sweat about her head. On the third day she had much pain in her bowels, with undigested, thin, and copious evacuations. On the fourth she had another rigor, and was worse on this and the fifth and sixth days. On the seventh she had a third rigor with high fever, much thirst, restlessness, and a cold sweat toward evening, when her limbs became cold and she could no longer be kept warm. In the night she had another rigor, her limbs could not be warmed, she did not sleep, but was delirious, although afterward she became collected. On the eighth she became warm again, was thirsty, comatose, had nausea, and vomited small quantities of yellowish bile, passed large quantities of urine unconsciously, and did not sleep. On the ninth she was comatose toward evening, had slight rigors, and small vomitings of bile. On the tenth she had another rigor, with much fever, did not sleep at all, but in the morning passed much urine with a sediment, and her limbs became warm. On the eleventh she vomited verdigris-green bile, and not long after had another rigor, with cold limbs. In the evening she had another chill, a cold sweat, much vomiting, and passed a painful and restless night. On the twelfth she had copious black, fetid vomitings, much hiccup, and excessive thirst, which were repeated on the thirteenth, when she had still another rigor and loss of speech. On the fourteenth blood ran from her nose and she died.

Case VI.—A woman, on the third day after the delivery of a daughter, the lochial discharge not taking place, was seized with an acute fever, and rigors, which were repeated up to the eighth day, when she was very incoherent, and had copious, thin, bilious stools, without thirst. On the eleventh she was disposed to coma, and her urine was copious, but thin and black. She had no sleep, and on the twentieth slight chills set in again, but she soon became warm. On the twenty-seventh day she was free from fever and was constipated, but not long afterward had violent pain in the hip, followed by renewed fever. Her urine was pale, watery, and copious. On the fortieth day she had cough with copious watery sputa, and had fever in an irregular form, sometimes present and sometimes not. The right side of her face was convulsively retracted, her passages became scanty and bilious, her fever more acute, and she often had rigors. She lost her speech, became comatose; then became collected again and talked rationally, but soon again became incoherent. Her urine was always black, thin, and watery, and on the fiftieth day she died.

Case VII.—A young woman was seized with an ardent fever, was thirsty, could not sleep, and menstruated for the first time. On the sixth day she had much nausea, was chilly, followed by flushing, and tossed about, and continued so on the seventh, when her urine was thin but of good color, and her bowels were not disturbed. On the eighth she was deaf, had high fever, was insomnolent, with nausea and rigors, all of which continued up to the fourteenth day, when she was delirious; but her fever had abated. On the seventeenth she had copious bleeding from the nose, and her deafness was slightly better; but on the following days the nausea, deafness, and incoherence returned. On the twentieth she had a small hemorrhage from her nose, and a sweat followed by apyrexia, when her delirium and deafness left her; but she had pain in her feet. On the twenty-fourth the fever and deafness returned, she was incoherent, and the pain in the feet persisted. On the twenty-seventh she had a copious sweat, followed by apyrexia, her deafness left, and the pains in her feet were lessened.

Case VIII.—A young unmarried woman was seized with an acute and ardent fever, insomnolency, thirst, constant nausea, dry and sooty tongue, and scanty, thin urine. On the third and following days she had copious watery, greenish stools, with some relief, but her urine remained scanty and she became delirious. On the sixth she had a great hemorrhage from her nose, and a chill, followed by copious hot sweat all over. The rigors were

are exceptional with most physicians; at least this is true of this city, where, as a professional friend aptly expressed it, "The cases of typhoid fever are too few to go around." The actual frequency of the disease in this city cannot be ascertained, but the most liberal estimate, based upon the number of deaths reported to the Board of Health, will not amount to more than from two thousand to three thousand cases annually. As a considerable proportion of these cases are treated in hospitals and by a comparatively few physicians in large practice, it is evident that most members of the profession in this city have no adequate opportunity to become familiar with the disease in the great variety of aspects it presents in different cases.

incoherently and had no sleep. On the eleventh she had wild delirium, her urine was black, thin, scanty, and oily, and she had copious, thin, diarrhœic stools. On the fourteenth she had frequent convulsions, her extremities were cold, her mind always wandering, and her urine was suppressed. On the sixteenth she had loss of speech, and on the seventeenth she died. The uterus was inflamed, and the head affected by sympathy.

Case X.—A woman, from sorrow, was seized with an acute fever with chills. From the first to the last she wrapped herself up in her bed-clothes, which she fumbled, picked, bored, and gathered threads from. She was silent, or broke into tears, or else laughed; she had no sleep and her bowels were irritable, although she passed nothing from them; her urine was thin and scanty, and she only drank a little when ordered to. She did not feel very warm, and her limbs were cold. On the ninth day she talked much and incoherently, and then became more composed and silent. On the fourteenth her breathing became slow and deep at intervals, and then again hurried. On the sixteenth, after a stimulant clyster, she had looseness of her bowels, passed urine involuntarily, and became completely insensible. Her skin was parched and tense. On the twentieth she talked much, her respiration was hurried; then she lost her speech, and soon died. Her respiration was often slow and large and deep, and then hurried; she always wrapped herself up in the bed-clothes, and either talked very much or was completely silent. This is regarded by commentators as a vivid and accurate description of a fever complicated with meningitis, or congestion and effusion on and in the brain. The Cheyne-Stokes respiration also attracted the attention of Galen. All these cases were treated by bleeding in the early stages; by clysters and injections of the bowels; and by suppositories, or so-called medicated pessaries, in the vagina. Affusions of hot water on the head were regarded as useful in all fevers except the bilious; fumigations to the uterus were also used. Warm baths, too, were given in acute diseases. Purging electuaries were used if the patient was young and strong; clysters only every three days, if the patient was weak. Hippocrates says if *erysipelas of the womb* seizes a puerperal woman, it will probably prove fatal.

SUPPRESSION OF A MEDICAL JOURNAL.—Dr. Grant-Bey, writing to the Albany *Medical Annals*, states that the Egyptian government has suppressed the *Shifa*, a journal published in Cairo in the Arabic language. First the subscriptions were withdrawn, and then, finally, notice of suppression was served. The article which was offensive to the British government in Egypt was an account of a visit by Virchow to Dr. Grant-Bey, in Cairo, written by the latter, and discussing the nature of cholera and the necessity of strict quarantine on every arrival from India.

CENTENARIANS.—A family of centenarians has just been brought to notice by a statistician. The seat of this remarkable family was at Tarbes, in the Department of the Hautes-Pyrenées, where its last survivor, Joseph Ritas, has departed this life one hundred and eighteen years of age. Ritas was born in Spain on August 21, 1770. His father lived to the age of one hundred and eleven years, and his brother died a few years ago at the age of one hundred and fourteen. The mother and paternal uncle of Ritas were equally long-lived, having far outstepped the allotted span of ordinary mortals. Lubicz Kurkovski, a Polish officer, has just died at Makoff, at the age of one hundred and sixteen years. It is stated that his age is authenticated beyond doubt. He was born in 1772. As the last survivor of the period when Poland was an independent kingdom, the death of Kurkovski has attracted great attention, and his funeral was attended by Polish gentlemen from all parts of Galicia.—*The Lancet.*

HYDROPHOBIA IN PARIS.—In the first five months of 1888 there were two hundred and eighty applicants at M. Pasteur's laboratory from the department of the Seine alone, all of whom had been bitten by dogs either known to be rabid or suspected of being so. This number is almost equal to the corresponding total for the whole year 1887, which amounted to three hundred and six. The Prefect of Police has, therefore, issued an order that for six weeks no dog shall be allowed to go about the streets of Paris, unless led by a string.

DEATH IN THE COURT PLASTER.—The "isinglass court plaster," that is so much in vogue with the laity and dilettanti medicals, is a material most plenteously pregnant for evil. It furnishes an ideal atmosphere and pabulum for bacteria, and has sent many an unfortunate to the ground. It is questionable whether it can be disinfected so as to be safe. Phlegmon, pseudo and true erysipelas are its most usual companions. Its most frequent victim being the accommodating and officious person (or his friends) who carries it about his person for emergencies, and who dispenses it with a "lick and a stick."—DR. A. R. JENKINS, in the *Annals of Surgery.*

THE REFORM OF CIRCUMCISION.—The Israelites of Paris recently appointed a commission of surgeons, under the presidency of Zadoc Kahn, the Grand Rabbi, to consider what modifications might advantageously be introduced in the ritual of circumcision. They have published rules looking to more thorough cleanliness of the operator, of his instruments, and of the infant, and have decided to do away with the sucking of the wound after the operation.

SOMETHING WRONG WITH THE BABY.—Dr. J. H. Straughn, of Lexington, Mo., writes that a woman sent for him to examine her new-born child, for she thought "there was something wrong." The child had an enormous caput succedaneum, double club-foot, umbilical hernia, spina bifida, and a supernumerary finger.

THE PRACTICE OF MEDICINE IN BALTIMORE.—Dr. E. M. Reid, of Baltimore, in an address on Medical Jurisprudence before the American Medical Association, says: "A school or college must be of good standing to be allowed to issue diplomas, but any ignoramus can hang out a sign and otherwise advertise as a doctor without having suitably prepared himself to perform the duties of one. In Baltimore an ignorant man, who had served a doctor in a menial capacity, and had had no opportunity to gain knowledge except such as could be acquired in sweeping the office and emptying spittoons, after his employer's death hung out his shingle, and commenced the practice of medicine on his own account."—*Maryland Medical Journal.*

A SOCIETY FOR THE SUPPRESSION OF QUACKERY exists in Holland. It is said to be in danger of dissolution owing to the heavy expense incurred in prosecuting charlatans, and in defending itself in the numerous libel suits which the exposed quacks bring against it.

ORIGIN OF THE MEDICAL AND SANITARY SERVICE IN RUSSIA.—Catherine II., of Russia, is said to have established, by imperial ukase, in 1762, hospitals in the cities and large towns for the reception of cases of contagious disease. She also established the foundling asylum in Moscow in 1764, and a home for the aged, and hospital for chronic diseases in St. Petersburg. Finally, in 1779, she opened an asylum for the insane. Previous to her time, it is said, there was no public medical service in that country.

HÆMOPHILIA AND CIRCUMCISION.—It is stated in a French medical journal that the Talmud provides that, in case two children in one family have died from hemorrhage following circumcision, any subsequent male children shall not be circumcised.

A TAIL IN THE HUMAN SUBJECT.—Dr. Piatnitsky reported the case of a peasant, aged twenty-three, who came to see if anything could be done to relieve him of a tail, which was a source of chagrin as well as of inconvenience to him. In the anal groove was a cylindrical tumor, about three inches long and three-fourths of an inch in diameter, covered with rather long hair. The tumor, which was attached to the coccyx, was removed. It was composed of a connective-tissue stroma, with vessels and nerves and striated muscular fibres arranged in three bands in each half of the appendix. Most of the muscular fibres had undergone fatty degeneration. The presence of muscular tissue led the reporter to regard the tumor as a true caudal appendix, and not as a simple new-growth. —*Meditsinskoye Obozreniye.*

ENTRANCE OF AIR INTO A VEIN.—At a meeting of the French Surgical Society on July 4th, M. Reynier said that he had recently removed a mass of enlarged glands from the neck, and during the operation had heard a gurgling sound like that produced by the entrance of air into a vein. No bad effects were noticed at the time, but on the third day, while dressing the wound, he heard the sound again, and the patient suddenly died. At the autopsy a small opening was seen in the internal jugular vein, and the vessel was seen to contain a number of bubbles.

PILOCARPINE IN DEAFNESS.—Pilocarpine would appear, according to Corradi, to be very serviceable in the treatment of deafness due to labyrinthine derangements, whether associated or not with disease of the middle ear. Large doses may be required. In one case two centigrammes of pilocarpine were injected twenty-four times. Moos has injected from five to eight drops of a two per cent. solution in cases of deafness resulting from diphtheria. Considerable improvement of hearing resulted even in cases in which deafness had existed for three weeks. Care is required lest the pilocarpine should increase the debility of post-diphtheritic cases.—*The Lancet,* July 21, 1888.

QUININE IN CHOLERA.—Dr. Lawrie, the Residency Surgeon in Deccan, asserts that quinine in three- to five-grain doses three times a day is an efficient preventive of cholera.

MICRO-ORGANISMS IN THE HOSPITAL WARD.—In order to determine the best place for the ventilators in a surgical clinic in process of building, Dr. Durante instituted some experiments in the wards of the hospital to ascertain at what level the air contained the greatest number of micro-organisms. Dr. Neri, who conducted the experiments, found that this point was about three feet above the beds. A great number of microbes were here found, the most numerous of the pathogenic ones being the Staphyloccus pyogenes aureus and Fehleisen's Empipelas streptococcus.

POTASSIUM PERMANGANATE IN AMENORRHŒA.—Dr. P. W. McDonald relates several cases in *The Practitioner* for June, 1888, of amenorrhœa associated with mental disease, in which permanganate of potassium, in doses of one or two grains three times a day, was prescribed. In six of the nine cases the mental faculties and utero-ovarian functions were restored, in three the utero-ovarian functions but not the mental equilibrium. In two of these three cases the menses ceased some time after the pills were discontinued. The writer believes that in these cases the remedy was stopped too soon, and he says that the permanganate should be continued for at least three months after the catamenia appear, and on no consideration should the patient cease taking it between the periods.

THE MICROBE OF CANCER.—Dr. Lampiasi-Rubino has

thin and scanty, [illegible]

day she had a slight rigor, followed by high fever, and a faint cold sweat about her head. On the third day she had much pain in her bowels, with undigested, thin, and copious evacuations. On the fourth she had another rigor, and was worse on this and the fifth and sixth days. On the seventh she had a third rigor with high fever, much thirst, restlessness, and a cold sweat toward evening, when her limbs became cold and she could no longer be kept warm. In the night she had another rigor, her limbs could not be warmed, she did not sleep, but was delirious, although afterward she became collected. On the eighth she became warm again, was thirsty, comatose,

ANTIPYRINE IN WHOOPING-COUGH.—Antipyrine, in doses of one to three grains in raspberry syrup, is recommended by Sonnenberger as an excellent remedy for pertussis.

ADDISON'S DISEASE.—At the conclusion of an interesting paper on this subject, Dr. McMunn remarked that as the animal body became more complex in the course of development, and a greater abundance of respiratory pigments became necessary for internal and ordinary respiration, certain organs had to be set apart, or had to take a new function, in the increased "division of labor." This function in the case of the suprarenal capsules was the removal from the circulation of useless and worn-out pigments. When the adrenals are diseased, these effete pigments and effete proteids circulate in the blood; the former, or their incomplete metabolites, producing pigmentation of skin and mucous membrane, and appearing often in the urine as urohæmato-porphyrin; the latter producing toxic effects, and leading to further deterioration of the blood with its consequences.—*Medical Recorder,* May 21, 1888.

CREOLIN is praised very highly by Dr. Heinrich Rausche as an antiseptic of undoubted power, which is harmless to the human organism. It furthermore possesses the advantage of cheapness, and does not stain instruments like corrosive sublimate. It is used in one-half to three per cent. solutions.

ON SOME DIFFICULTIES IN THE DIAGNOSIS OF TYPHOID FEVER.[1]

BY A. BRAYTON BALL, M.D.,

PHYSICIAN TO THE NEW YORK AND ST. LUKE'S HOSPITALS.

I HAVE some hesitation in presenting for discussion this evening so well-worn a theme as the diagnosis of typhoid fever, but the difficulties of the subject are so great that even a restatement of old facts may not be unprofitable. As Liebermeister has well observed, "The more one believes in the possibility of error, the surer will he be to avoid mistakes."

Although well-marked typhoid fever, with fully developed symptoms, and running a typical course, is not likely with ordinary care to be mistaken for any other disease, except at the outset, it is still true that there are few affections of common occurrence in which errors in diagnosis are so frequent. The explanation is not difficult. Typical typhoid fever is the exception rather than the rule; most cases deviate more or less from what may be called the normal type. Furthermore, the opportunities for studying these deviations in a large number of cases are exceptional with most physicians; at least this is true of this city, where, as a professional friend aptly expressed it, "The cases of typhoid fever are too few to go around." The actual frequency of the disease in this city cannot be ascertained, but the most liberal estimate, based upon the number of deaths reported to the Board of Health, will not amount to more than from two thousand to three thousand cases annually. As a considerable proportion of these cases are treated in hospitals and by a comparatively few physicians in large practice, it is evident that most members of the profession in this city have no adequate opportunity to become familiar with the disease in the great variety of aspects it presents in different cases. It is not surprising, therefore, that the doubtful nature of the symptoms in the early stage, and a natural reluctance to excite alarm by suggesting the possibility of so serious a disease as typhoid fever, should often mislead the physician at the outset into giving an erroneous opinion, that is persisted in, or only vaguely modified, when the real nature of the attack is revealed in the light of later developments.

While it is true of typhoid fever, as of other specific infections, that its symptoms tend to conform to a general type, nothing is more essential to its correct diagnosis than a recognition of the equally important fact that the picture of the disease may be widely different in different cases. As Jürgensen[2] has pointed out, the very inclusion of enteric fever in the category of infectious diseases implies the occurrence of all grades of severity in the symptoms, no less in this affection than in scarlatina, measles, and small-pox. Since the disease is a reaction between a specific virus and an extremely variable individual factor, we must expect to find all shades of intensity in the morbid process, from the fulminant forms in which the system is overwhelmed from the start, to those milder types in which there are merely slight disturbances of a few days' duration, so uncharacteristic that their true nature can be determined only by etiological considerations. Moreover, it cannot be insisted upon too strongly that, aside from the detection of the typhoid bacillus, there is no pathognomonic symptom of typhoid fever. Every one of the symptoms, even those upon which we place the most reliance, is found with greater or less frequency in other affections; so that in typhoid fever, more than in most diseases, the diagnosis must rest upon the significance of the symptoms as a group, rather than upon the pathognomonic value of any individual member of it.

In a certain proportion of cases—and this proportion seems to vary in different epidemics and in different localities—typhoid fever instead of presenting its usual gradual access is ushered in suddenly with a rigor or marked chilly sensations, and a rapid rise of temperature to 103° or 104° F. within the first twenty four or forty-eight hours. Wunderlich's well-known dictum, that typhoid fever may be excluded when the temperature is 104° on the first or second day, is doubtless true for the great majority of cases, but the exceptions are too numerous for the rule to be an absolutely safe guide. This sudden access of symptoms appears to be determined sometimes by a malarial complication—certainly this is the interpretation usually put upon it—but it does occur also in cases which at no time during their course present any evidence of malarial infection. Thus, a rapid onset is occasionally seen in those very acute cases which resemble the fulminant forms of typhus; it occurs also in cases of moderate severity with protracted course; but the point to which I wish to call special attention is this, that a sudden outbreak of symptoms is observed occasionally in the very cases which are most likely to present difficulties in diagnosis, viz., in the abortive forms, in which characteristic symptoms are often absent, and the termination of the attack at the end of the first or second week leaves us in more or less doubt as to the nature of the illness. Jürgensen's statistics [1] upon this point are instructive. They include eighty-seven cases of abortive typhoid fever occurring alongside of pronounced forms of the disease in house and hospital epidemics, under conditions, therefore, which made the diagnosis reasonably certain. Of these eighty-seven cases there were

ENDED.		BEGAN.		
		Suddenly.	With Shivering.	Gradually.
On 4th to 7th day,	16......	All	9	None
On 8th to 10th day,	19.....	All	11	None
On 11th to 13th day,	24......	20	11	4
On 14th to 16th day,	28......	19	11	9

In eighty-five per cent., therefore, the attack began suddenly; in nearly half the number it began with a distinct rigor or chilliness, so that the patient could name the first day of his illness, while in all the cases that terminated before the eleventh day a gradual onset of symptoms was not recorded once. My own impression, though I have no statistics to present, is, that in this country abortive typhoid fever presents prodromic symptoms with greater frequency than was observed in Jürgensen's cases; but there is no doubt, I think, as to the general correctness of his statement. Fortunately these abortive cases usually show symptoms that are fairly characteristic, such as enlargement of the spleen, slight diarrhœa, and an early crop of rose-spots; but these signs may all be absent in cases that are apparently due to typhic infection. A single illustration must suffice:

---

[1] Loc. cit.

In a family in which a husband and wife were both ill with severe and protracted typhoid fever, the wife's brother, after a few days' malaise and headache, took to his bed with a slight fever. During the following week the temperature ranged between 99° and 101.4° F., at no time rising above the latter point. The general prostration and hebetude were disproportioned to the temperature, but there were no other symptoms that would suggest typhoid fever; no meteorism or diarrhœa, no rose-spots, and no appreciable enlargement of the spleen. The patient had been in perfect health up to this time, and careful examination failed to reveal any cause for the fever except a very mild typhic infection. The fever defervesced at the end of the first week, practically without medication, and convalescence was established within a short time. Abortive cases of typhoid fever, occurring independently of conditions likely to excite suspicion, are much more frequent than is commonly supposed; and when quinine is used freely, as is generally the case, the physician too often regards the malarial nature of the attack as demonstrated by the apparent arrest of symptoms, or congratulates himself on having cut short an attack of typhoid fever.

Much importance has been attached, and I think justly, to the peculiar physiognomy and manner of typhoid-fever patients during the first period of the disease. The grave and serious aspect of the countenance, the air of listless indifference, the brief replies to questions without attempts at explanation, the avoidance of unnecessary motion, the dilated pupils, and the dusky pallor, or, perhaps more frequently, the hectic flush of the cheeks, constitute an *ensemble* of symptoms that is very characteristic in well-marked cases. It is important to remember, however, that these symptoms are due, not to the mere elevation of temperature, but to oppression of the nervous system by the typhic poison, and that in milder grades of infection, even with high temperature, a natural buoyancy of temperament may be preserved throughout the attack. I recall especially one case in which, notwithstanding an afternoon temperature of 104° F. for several days, the patient manifested a gayety of manner that would have allayed suspicion if the occurrence of some diarrhœa and a fairly marked roseola, together with the presence of two pronounced cases of typhoid fever in the same family had not confirmed the diagnosis.

So, too, with the temperature curve of typhoid fever, we must expect to find frequent deviations from the usual type with its triple series of oscillations—one of ascending, one of stationary, and a third of descending oscillations. To be sure, the temperature curve in this disease derives its only value from its greater or less conformity to the general type; but it should be borne in mind that the temperature equilibrium of typhoid fever is particularly unstable, and that the schematic curve which is depicted in text-books to show what the course of the temperature in typhoid fever ought to be, but which one rarely sees anywhere else, is apt to be changed by a great variety of disturbing influences. Thus, as we have already seen, the period of ascending oscillations may be absent, in consequence of the rapid onset of symptoms. The final series of descending oscillations may also be lost from a termination by a comparatively rapid or irregular lysis; while in the intervening period the usual curve of stationary oscillations may be broken by sudden falls or rises, due to the action of medicines, mental emotion, physical exertion, errors in diet, hemorrhages, malarial complications, and other causes, the nature of which is not always clear. The greatest diagnostic value belongs to the period of descending oscillations, when this assumes a markedly intermittent type, with nearly or quite normal morning temperatures, and high evening temperatures slowly descending to normal through a period of several days. Such a course of the final temperature in the third or fourth week of a fever is fairly pathognomonic of typhoid fever, as it is rarely found in other febrile affections. In private practice this characteristic termination of the curve is often lost by a failure to take the afternoon temperature, on account of the favorable condition of the patient at the usual morning visit. The typical curve may be altered, also, by the assumption for one or more days of the "inverse type," with temperatures higher in the morning than in the evening; also by a general depression of the curve, with oscillations not rising above 101° or 102° F. throughout the attack, and, finally, by the absence of any rise above the normal. Several epidemics of typhoid fever, in which a certain proportion of the cases were afebrile during the whole course of the disease, have been recorded by such competent observers as Strube, Liebermeister, Friedlander, and others.

The roseola of typhoid fever, when typical in form and recurring in successive crops, is a most valuable aid in diagnosis. Except in children, it is found in a large proportion of cases occurring in this part of our country, but with a frequency varying according to the severity of the epidemic type. In Western, and particularly in Southern States, it seems to be observed less frequently, even in cases presenting other characteristic symptoms of the disease. The eruption is overlooked sometimes through ignorance of the fact that the favorite site is not on the abdomen, as is commonly supposed, but on the dorsal region of the back, where the spots, in some cases, may be found when they are absent elsewhere. When the eruption is present, and especially if it be copious, some of the spots often fail to answer to the usual description, and may be mistaken for "ordinary pimples" or flea-bites, though they never show the central dot which characterizes the latter eruption. Such irregular forms—if they may be so called—may be distinctly elevated or even acuminated, they may last longer than the usual limit of three to five days, they may fail to disappear on pressure, and, as Jenner pointed out, in rare instances they may present a minute vesicle at the apex. Still, no diagnostic importance can be attached to any spots that are not typical, and the only safe way to guard against mistake is to surround each suspected spot with a circle drawn with ink, an aniline pencil, or nitrate of silver, and then study its changes from day to day in connection with the appearance of rose-spots elsewhere. Typical rose-spots recurring in successive crops are fairly conclusive evidence of typhoid fever; and yet it should be noted that, according to Rilliet and Barthez, and Bouchut, a similar roseola is found not very infrequently in children with acute miliary tuberculosis, and that Murchison and Senator have each recorded a case of the same disease in adults with rose-spots that could not be distinguished from those of typhoid fever.

Enlargement of the spleen, when not due to cardiac, pulmonary, or liver disease, is merely evidence of some infective process, and has only this diagnostic significance, which is yet a very important one. When the tumor is of moderate size it is of little service, therefore, in distinguishing typhoid fever from other affections in which similar enlargements are found. In malarial infection the splenic tumor is usually larger than in typhoid fever, but a considerable enlargement is occasionally seen in the latter affection, especially when it attacks young children. Splenic enlargement is met with also in general tuberculosis, septicæmia and pyæmia, malignant endocarditis, and other infective processes; but, as a rule, it is not found in simple gastro-enteric catarrh, in ephemeral fever due to various non-infective causes, or in symptomatic fevers, between which affections and typhoid fever, therefore, the presence or absence of enlargement of the spleen may be of much assistance in diagnosis. So much uncertainty, however, attends the physical examination of the spleen in the presence of distention of the stomach and intestines that this sign is not available in many cases. On careful palpation the projecting edge of the spleen may be felt occasionally when we have demonstrated apparently the absence of enlargement on percussion.

The presence of constipation, in place of the usual diarrhœa with pea-soup stools, often proves to be another source of difficulty in diagnosis. The absence of diarrhœa seems to have been specially frequent in the forms of typhoid fever seen in this region during the past ten years. In fact, it has been no uncommon experience to meet with cases in which the proper emptying of the bowels, without resorting to cathartics, has been the chief embarrassment in treatment. This difficulty is encountered, of course, more frequently in mild cases; but it is met with also in severe types of the disease. I have seen fatal peritonitis produced by perforation of a typhoid ulcer in a patient who had at no time presented diarrhœa, but had required daily enemata, the diagnosis being confirmed by autopsy. In another well-marked case the constipation that had persisted throughout the attack resulted, after a constipated stool, in an anal fissure that subsequently required incision to cure it. Moreover, when diarrhœa does occur, it may be slight, or uncharacteristic in the appearance of the stools, or it may develop at a late period after typhoid fever has been excluded from the diagnosis by reason of the atypical nature of the symptoms.

We are so much in the habit of regarding typhoid fever as essentially and predominantly an enteric process that we are apt to forget that it is also a general infection, and are not always prepared, therefore, to recognize the significance of other localizations when these press to the front in the early stage, and the intestinal symptoms remain for a time in the background. In such cases the usual picture of the disease may be changed, at the outset, almost completely, by the attack being ushered in with marked pulmonary, renal, or cerebral symptoms, the true nature of which may be revealed only by the later development of meteorism, diarrhœa, and roseola. The prominent part which lesions of the respiratory tract—pharyngeal catarrh, bronchitis, and pneumonia—often play in this disease, especially during the second or third week, is well known; but the fact is less familiar that, in certain cases, pulmonary symptoms may assume such prominence from the start as to disguise, at least for a time, the real character of the illness. Thus, the attack may begin with a catarrhal pneumonia in such massive form as to present all the signs of croupous pneumonia, or more commonly with a bronchitis, so marked as to disarm suspicion of any other cause for the fever.

Last autumn I saw in consultation a girl, twelve years of age, who had been ill for two weeks with obscure symptoms. The attack began with sore throat, followed by a cough which had steadily increased in severity, and of late had become very distressing. There had been some fever, but its type could not be ascertained on account of the irregular attendance of her physician. Except some loose stools on one day, due to action of a cathartic, there had been no diarrhœa. The marked loss of flesh and urgent character of the pulmonary symptoms had excited suspicion of an acute miliary tuberculosis; in fact, such a diagnosis had been given to the family. At the time of my visit, two weeks after the first symptoms, the child was about the house, and had not been confined to bed, although evidently seriously ill. She was thin; her face flushed and somewhat cyanotic; pulse, 120; respirations between 40 and 50; temperature normal (morning). The cough was incessant, and accompanied by only slight mucous expectoration. Physical examination of the lungs gave only signs of bronchitis. There were no rose-spots, meteorism, or diarrhœa. The child was quite deaf in both ears, much more so than could be accounted for by the small amount of quinine she had taken, and this fact excited my suspicion that, although the symptoms thus far appeared to be wholly pulmonary, we really had to deal with a typhic infection. The absence of fever seemed to contraindicate such a diagnosis, but there was a history of fever, and it was possible that this remission might be accidental. The child was put to bed. In the evening of the same day the temperature rose to 104° F.; roseola developed two days afterward, with meteorism and diarrhœa, and from that time on the disease ran its usual course, with relief to the pulmonary symptoms when diarrhœa set in. Subsequently she had a relapse, ushered in by the same urgent bronchitis noticed in the primary attack, but followed by complete recovery of health.

A second very similar case may emphasize this lesson. A young lady, twenty-one years of age, after a month's residence in Florida this spring, complained of some malaise during the last days of her visit, and was supposed to have caught cold at a lawn party the day before she returned to this city. On her arrival here she had some sore throat and a very troublesome cough, for which she consulted her physician. I saw her two weeks after the appearance of the first symptoms. During the preceding three or four days she had been chilly at times, and somewhat feverish, but had not been confined to bed and complained of nothing except a very severe cough. This was incessant, with only trifling mucous expectoration. There had been no abdominal symptoms, no epistaxis, only slight headache, and no more malaise than often occurs in connection with bronchitis. Her temperature, however, was 103° (evening), and her general aspect, together with the marked resemblance of her peculiar cough to that of the previous case, impressed me with the possibility of typhoid fever. On the following day there were increased malaise and marked hebetude. Two days later a few rose-spots appeared on the dorsal region of the back, followed forty-eight hours afterward by successive crops on the abdomen, meteorism, diarrhœa, and the usual train of typical symptoms. In this case also there was marked relief to the cough on the development of abdominal symptoms. The fever defervesced completely on the thirtieth day. After an interval of thirteen days her cough returned with considerable urgency, and for forty-eight hours this was the only symptom that excited suspicion of a relapse, except a slight acceleration of the pulse and a temperature that did not rise above 100° F. After this time the bronchitis persisted as the most prominent symptom, until the appearance, on the fourth day of relapse, of marked meteorism, and some tenderness in the right iliac region, but without recurrence of the diarrhœa. Another case of typhoid fever, contracted in the same hotel at about the same time, was sent to one of our city hospitals, and had a sharp attack, with diarrhœa and intestinal hemorrhages.

The resemblance between these pulmonary forms of typhoid fever and a pulmonary tuberculosis is often so close that a differentiation between them by the symptoms alone is impossible. In illustration two cases may be quoted; the first of which was reported by Murchison.[1]

Female, aged twenty-five years. Mother died of consumption. Patient had had a cough for one year, with emaciation and night-sweats. Twelve days before admission to hospital her symptoms had become much worse; increased cough, fever, profuse perspirations, rapid emaciation, and great prostration. On admission every appearance of advanced phthisis; pink flush on cheeks; pulse, 120 to 140; temperature, 101 to 103.5°; respirations, 40; great dyspnœa, profuse expectoration of creamy pus; tongue dry and red; abdomen flat; no diarrhœa or rose-spots; constant delirium. Four days afterward hemorrhage from the bowels, and death forty-eight hours after. The autopsy revealed typical typhoid ulcers in the lower part of the ileum, and no tubercle anywhere. Lungs congested; commencing lobular pneumonia in both inferior lobes. "At the entrance of larnyx there were several small ulcers, the largest forming a deep excavation in front of the epiglottis, and being the apparent source of the pus which was expectorated during life."

The reverse of the picture is shown by an equally striking case reported by H. Senator.[2] In this patient there were no pulmonary symptoms until five days after admission. Well-marked catarrh then developed, but the other symptoms seemed to point unmistakably to typhoid fever. There were present, during the course of the attack, enlargement of the spleen, successive crops of rose-spots, several epistaxes, dicrotic pulse, deafness, meteorism, and suppurative parotitis. On ophthalmoscopic examination nothing abnormal was found except paleness of the fundus. At the autopsy there was no typhoid lesion, but miliary tuberculosis of both lungs and bronchial glands, as well as of the enlarged spleen, liver, and kidneys.

[2] "Ueber einen Fall von acuter Miliartuberculose mit dem ausgeprägten Bilde des Abdominaltyphus," Berliner klin. Wochenschrift, 1881, 349.

In all forms of tuberculosis, whether pulmonary, peritoneal, or cerebral, the fever is usually of a different type from that of typhoid fever. As Dr. Waters, of Liverpool, has pointed out, it commonly attains its maximum at or before 5 P.M.; while in typhoid fever the temperature is generally higher at nine than at five o'clock. Moreover, an inverse type of temperature is much more common in tuberculosis than in enteric fever. Brunniche [1] lays special stress on this point, as he found it fifteen times in seventeen cases of acute miliary tuberculosis. This proportion is doubtless much larger than is commonly found, and it is to be borne in mind also that the typus inversus is occasionally met with in enteric fever, though rarely for longer than one or two days at a time. These are specially the cases in which search for the tubercle or typhoid bacilli is desirable, and sometimes affords the only means of positive diagnosis.

Another localization of the typhic process which may give rise to difficulties in diagnosis is the renal type, first described by Gubler and Robin, and known as the Gubler-Robin form of typhoid fever.[2] In these cases renal symptoms may assume in the early stage a predominance over other symptoms that may suggest acute nephritis rather than typhoid fever. In well-marked forms the attack may begin with a rigor or chilly sensations, general depression, and repeated epistaxes. The face is often pale, occasionally bloated, with some swelling of the feet, but no general anasarca. The pulse is often as tense as in acute nephritis. The urine is scanty and contains a large amount of albumen, with blood, epithelial, and granular casts. When these symptoms usher in the attack the diagnosis must remain in doubt temporarily until abdominal symptoms develop, as they usually do later. Amat takes a discouraging view of the prognosis of these cases, and says that five-sixths of them die in the second week; but this is probably an exaggerated statement, as it is not confirmed by other writers. These renal symptoms, like the pulmonary symptoms, often subside on the appearance of diarrhœa, and severe lesions of the kidneys are rarely found at the autopsy.

So, too, much embarrassment may be occasioned by the early development of nervous symptoms, cerebral or spinal. Murchison [3] reports a case of a man, aged forty, "who after a few days' malaise, which attracted but little notice, passed suddenly into a state of maniacal delirium, requiring two men to hold him down in bed." After a dose of chloral he slept well, and from this time the fever ran its usual course. In his classical work on the "Fevers of Great Britain," he states that he has seen a considerable number of cases in which delirium was the first symptom observed, and that in two of the cases removal to a lunatic asylum had been contemplated. Several instances in which such patients have actually been sent to asylums have been recorded by other observers.

Spinal symptoms may also predominate, in the early stage of typhoid fever, to a degree sufficient to excite suspicion of organic lesion of the spinal cord. As Fritz [4] has pointed out, such cases may present marked pains in the entire spinal region, extending into the extremities, stiffness of the neck, cutaneous and muscular hyperæsthesia, and even paresis of the lower limbs. In both the cerebral and spinal forms these early symptoms, as in the other atypical localizations, usually subside on the later appearance of enteric symptoms, and without appreciable lesions at the autopsy in fatal cases. Still, in exceptional instances, the nervous system may be overwhelmed fatally at the outset. Trousseau [1] reports a case that began very suddenly—the date of onset could be fixed accurately—with violent headache and insomnia, disturbed by frightful nightmares. She was brought to the hospital on the fourth day of her illness, suffering from racking headache, atrocious pains in the limbs and loins, intense fever, and rapid pulse. She died the same evening, and the autopsy disclosed one of the most confluent enteric eruptions Trousseau had ever seen.

Difficulties may occur also in the differential diagnosis between typhoid fever and acute rheumatism. Bourcy,[2] in a Paris Thesis, 1883, has reported a number of cases of typhoid fever in which during the course of the disease joint symptoms developed, resembling those of acute rheumatism, but which he regards as "typhoid in nature, and only apparently rheumatic." A similar case is reported by Wagner [3] with acute articular symptoms, involving several joints, appearing on the twelfth day of the fever. At the autopsy no pyæmic lesions were found in the joints.

In certain localities articular symptoms appear to be a very frequent complication of typhoid fever. Thus, Dr. Turner, of Gibraltar [4] in an article on the rock fever of that region—which he regards as a true enteric and not a malarial fever—states that articular symptoms, varying from slight tenderness of a single joint to an extensive febrile rheumatic affection, are present in a large proportion of the cases observed there. The frequency of this complication in Gibraltar he ascribes to the marked prevalence of rheumatism in that locality, and suggests that persons whose vitality is lowered by any protracted illness are, for this reason, specially liable to contract it. In his cases the rheumatic symptoms rarely developed before the end of the second week, usually during convalescence.

Again, acute rheumatism, or at least symptoms which cannot be distinguished from it, may occur coincidently with typhoid fever and for a time overshadow it. Dr. Finlay [5] has reported a very interesting case illustrating this fact. The patient before admission to the hospital had been ill for a week with fever, pain, redness, and swelling of his ankles, hips, and knees, and examination showed a well-marked mitral systolic murmur. He was treated with salicylate of soda, and the fever and joint symptoms disappeared five days after admission. A fortnight afterward the fever returned; rose-spots appeared six days later, with diarrhœa, and the patient died on the twelfth day of this attack The autopsy showed general peritonitis from perforation of a typhoid ulcer in the lower part of the ileum, and another ulcer, nearly healed, that was clearly of much earlier formation. It seemed probable, therefore, that the fatal attack was a relapse of typhoid fever, and that the primary one had coexisted with, and been concealed by, the acute rheumatism. He also reports three cases of typhoid fever occurring during convalescence from acute rheumatism, and suggests the query whether rheumatic fever may not, in some degree at least, predispose to enteric fever, though perhaps only in the general sense that all febrile processes may do so. In this connection he states that of seven patients in whom typhoid fever had developed in the wards of Middlesex Hospital during the preceding ten years, five had been admitted for undoubted rheumatism.

Moreover, acute rheumatism with marked fever, but with imperfectly developed joint symptoms, may be mistaken occasionally for typhoid fever. Wagner, in the article already quoted, mentions several cases in which the diagnosis fluctuated between typhoid fever, acute rheumatism, and cerebro-spinal meningitis for several days, until finally pronounced articular symptoms appeared, and yielded to the administration of salicylic acid.

Several questions of much interest are suggested by these observations on a subject that seems to have attracted but little attention until within the past few years, but we can delay only to draw the following practical conclusions: 1. That typhoid fever, like scarlet fever, though much less frequently, may present joint symptoms apparently rheumatic, but whether such symptoms are a manifestation of typhic infection, or indicate a complication with true rheumatism must be decided by the special conditions of the individual case. 2. That after an attack of acute rheumatism the development of typhoid fever, in more or less direct association with it, is to be borne in mind as a possibility. 3. That rheumatic fever, independently of typhic infection, may simulate the latter for a time so closely that only the result of treatment or the future progress of the case can clear up the diagnosis.

Perityphlitis usually differs from typhoid fever so widely in its symptoms and history that it may seem scarcely necessary to refer to the possibility of confounding the two diseases. Still, this mistake has been committed not very infrequently, and I have to confess having been myself a *particeps criminis* in such a blunder. Some years ago, on beginning my service at a hospital in this city, I found a convalescent patient who had been ill—so I was told by the house-physician—with an attack of perityphlitis in which resolution of the inflammatory process had occurred, as so often happens, without suppuration. My predecessor, now dead, a man of acknowledged skill and a careful observer, had made this diagnosis on account of the absence of the usual symptoms of typhoid fever, and the presence of an unusual degree of tenderness and some tumefaction in the right iliac fossa. The bowels had been constipated, rose-spots had not been found, the temperature curve had been uncharacteristic, and the slight fever had subsided at the end of the second week. The patient was kept in bed a few days longer, and then was allowed to sit up, but on doing so she was seized with a return of the pain in the right iliac fossa, accompanied by fever. During the following week, although no tumor could be detected, there was decided resistance to pressure, and both the right iliac fossa and the right flank were markedly tender. The bowels were obstinately constipated, there were no rose-spots, and the temperature was uncharacteristic. Deep-seated burrowing of pus behind the cæcum and ascending colon was suspected, and this opinion was confirmed by two attending surgeons, who saw the patient in consultation with me. The case was, accordingly, transferred to the surgical side, and two punctures for pus were made without success. During the night the patient fell into collapse and died the next day. At the autopsy no evidence of perityphlitis was found. There was commencing general peritonitis, and numerous typhoid ulcers were present in the lower part of the ileum, some partly healed, some evidently of recent origin, and one that had perforated the bowel, and had been evidently the immediate cause of death.

One attack of typhoid fever, as is well known, confers a certain degree of immunity from a recurrence of the disease. Instances of second attacks have been mentioned by Murchison, Bartlett, Budd, Liebermeister, and others, but rather as curiosities in medical experience, and the general impression seems to be that in a case with suspicious but not typical symptoms, the history of a previous attack may exclude typhoid fever with a considerable degree of certainty. The recent investigations of this subject by Eichhorst, of Zurich,[1] show, however, that recurrent attacks are much more frequent than is commonly supposed, and that even a third or a fourth attack may possibly occur. In an analysis of 666 cases of typhoid fever treated by him (1884–1886) he found a recurrence of the disease in 4.2 per cent. of his cases. From the Munich Hospitals Huber reports second attacks in 1.7 per cent. out of 457 cases (1865–1866), Körber in 1.6 per cent. out of 1,291 cases (1870–1873), and Beetz in 1.7 per cent. out of 599 cases (1874–1875). Eichhorst's statistics also fail to confirm the general impression that a second attack, when it does occur, is less severe than the first one. The mortality was as great, and the complications as numerous in the second attacks as were observed in the general typhoid fever statistics of the hospital.

The limits of this article will permit us to touch only very briefly on the diagnostic relations of typhoid and malarial fevers, a subject that has excited much controversy, and is admitted to present serious difficulties. The attempt, however, to adjust some of these difficulties by the introduction of a new category of fevers—typho-malarial fever—has proved unsatisfactory in many ways. As originally proposed by Dr. Woodward, in the late war, this term was intended to be restricted to cases in which there was reasonable evidence of infection with the special poisons of both malarial and typhoid fevers. It was in this sense only that typho-malarial fever was recognized as a distinct affection by the International Medical Congress of Philadelphia in 1876, and was introduced by the London College of Physicians into its nomenclature of diseases. It is not easy to see why a hybrid term is necessary here more than in several other diseases which we know are often complicated with malaria; but if such a term be actually needed, others are available which are less open to objection—such as "malarial typhoid fever," "malarial enteric fever," or, still better, as Dr. Squire, of London, suggests, "typhoid fever and malarial fever," "just as one would enter syphilis and scarlet fever if the two coexisted."[1] The term "typho-malarial fever" throws the emphasis on the malarial element, which must be, in the great majority of cases, the subordinate and less dangerous factor. Nor is this objection hypercritical. The practical result of the adoption of the term has been that with a large proportion of the medical profession "typho-malarial fever" has lost its original meaning, and has come to be regarded as merely malarial fever with typhoid symptoms. In fact, Dr. Squire, in his article on Typho-Malarial Fever,[2] actually defines it as "a *malarial fever which has assumed that adynamic type which is present in typhoid fever.*" According to this definition typho-malarial fever is a malarial fever without true typhic infection—the prefix "typho" having merely the meaning of "adynamic." Such a misuse of a term that has been employed in an entirely different sense for a quarter of a century cannot be justified, and only adds to the already existing confusion.

I say confusion, because I think no one can have seen many cases of typhoid fever in hospital or consultation practice without being struck by the very great frequency with which this disease is confounded with malarial fever, and that, too, not only in regions where malarial infection assumes its intenser forms, but perhaps also with almost equal frequency in localities where intermittent fever and other mild malarial affections prevail to a greater or less extent, but the poison is rarely severe enough to excite the remittent or continuous forms of fever. The explanation lies, I suspect, in a very prevalent bias in the minds of a large portion of the medical profession toward interpreting all febrile disturbances not clearly traceable to obvious lesion as malarial manifestations. That such a bias does exist, and that, by reason of it, typhoid fever is not recognized in a large proportion of cases are facts of common observation, though not susceptible of demonstration on a large scale except by indirect proof. Such evidence is presented, at least so far as the City of New York is concerned, by the following comparison of the mortality statistics of typhoid and malarial fevers in the city at large with the similar statistics of eight of our largest hospitals.

[1] Klinische Erfahrungen über wiederholtes Erkranken an Abdominaltyphus, Virchow's Archiv, Bd. cxi., Heft 1, 1888, 48.

[1] The American Journal of the Medical Sciences, April, 1887, p. 396.

[2] Loc. cit.

Annual mortality from typhoid, typho-malarial, and malarial remittent fevers in the City of New York, from 1883 *to* 1887, *inclusive, as reported by the Sanitary Bureau.*

	Typhoid fever.	Malarial remittent fever.	Typho-malarial fever.
1883	471	174	154
1884	389	119	77
1885	294	120	111
1886	325	151	108
1887	323	117	78
Total	1,802	681	528

In the published reports of the Board of Health typho-malarial fever is classed under the head of malarial fevers. Following this classification the record is, therefore: Total number of deaths from typhoid fever, 1,802; from malarial remittent and typho-malarial fevers, 1,209.

Mortality from the same diseases in eight hospitals in the City of New York for the quinquennium 1883–87.

	Typhoid fever.	Malarial remittent fever.	Typho malarial fever.
Bellevue Hospital	116	5	8
St. Francis' Hospital	78	0	0
New York Hospital	50	3	0
Roosevelt Hospital	41	0	0
St. Vincent's Hospital	25	3	0
Presbyterian Hospital	21	0	0
Mount Sinai Hospital	19	0	2
St. Luke's Hospital	16	0	0
Total	366	11	10

Following the Board of Health classification, the hospital record is, therefore: Total number of deaths from typhoid fever, 366; from malarial remittent and typho-malarial fevers, 21. In the city at large, according to the Board of Health statistics, the ratio between the mortality from malarial remittent and typho-malarial fevers, and that from typhoid fever, is 1 to 1.65. The relative mortality between the same diseases in the hospitals specified is 1 to 17.42.[1]

As the relative mortality of typhoid and malarial fevers must be approximately the same in our hospitals as in the city at large, and as the diagnosis of these affections in hospitals, where the cases are carefully studied, may be regarded as fairly accurate, only one conclusion can be drawn from the very striking contrast presented by the above tables. Nor is it merely a question of medical terms or comparative skill in diagnosis. In a disease requiring such careful management as typhoid fever, error in diagnosis implies also, in many cases, injudicious, perhaps harmful, treatment. The dangers from intestinal hemorrhages and perforation are not guarded against, while the spread of the disease in the community is favored by neglect of sanitary precautions. Indeed, it is difficult to exaggerate the serious importance of such mistakes, repeated as they are in many hundreds of cases every year in this city.

It should be noted also that the introduction of "typho-malarial fever" into the classification of fevers has made it impossible to ascertain the relative frequency of typhoid and malarial fevers. The Board of Health of this city classes typho-malarial fever under the general head of malarial fevers, and thus throws the weight of its authority in favor of the view that in this part of the country typho-malarial fever is essentially a malarial fever. Every one familiar with the facts knows that the great majority of cases so reported were really cases of typhoid fever, which were diagnosticated as malarial at the outset, a revision of the diagnosis being necessitated by the later development of symptoms more or less characteristic of typhoid fever. Still, even if the diagnosis in these cases be admitted as correct, there can be no doubt that in such combined infections the fatal element, at least in this part of the country, is the typhoid rather than the malarial poison. The Board of Health of this city is, of course, not responsible for the correctness of the diagnoses reported to it, but it can at least make its statistics less inaccurate than they are under its present classification of fevers, by removing typho-malarial fever from the general category of malarial fevers, and placing it in a nondescript class by itself.

As regards uncomplicated malarial remittent fever, the report of only eleven deaths in eight of our largest hospitals during the past five years—most of these deaths occurring in patients from Southern States or from regions farther south—shows clearly that malarial fever of a remittent type is far from being a prevalent endemic disease in this locality. On the contrary, I believe that it is comparatively uncommon, and that this diagnosis is made here so frequently mainly because there are so few opportunities for becoming familiar with its characteristic symptoms. It is unnecessary to enter into details of differential diagnosis; the only point I wish to emphasize is this, that, given a case of more or less continued fever in this city, the chances between typhoid fever and malarial fever are altogether in favor of the former, and that the burden of proof lies wholly on the malarial side. Doubtful cases do occur occasionally which require quinine as a test, but the better acquainted one becomes with the varied forms of typhoid fever the less occasion there will be to resort to the diagnostic use of this drug. I lay some stress on this point because the routine use of quinine in large doses in the early stage of fevers in this region is unnecessary for the great majority of cases, and is, therefore, objectionable for obvious reasons. Most of our hospital patients with typhoid fever have been thoroughly dosed with quinine before admission, even when the symptoms were typical from the outset.

In other localities, however, where malarial infection assumes a severer type, the differentiation of typhoid fever from malarial fever is much more difficult, and is embarrassed by the question whether uncomplicated malarial infection may present the adynamic and enteric symptoms of typhoid fever, or whether the occurrence of these symptoms in malarial fever implies infection with both poisons. This was the problem presented to the physicians in our Northern armies during the War of the Rebellion, when they met in Southern States a type of fever different from the typhoid fever with which they were familiar, and different also from the usual malarial remittent of the South. The first Commission, appointed in December, 1861, to investigate the nature of the fever prevailing in the Army of the Potomac, in front of Washington, reported that, while a certain number of cases of ordinary typhoid fever existed in the army, the large majority of the febrile cases were "bilious remittent fevers, which, not having been controlled in their primary stage, have assumed that adynamic type which is present in typhoid fever." This decision was reversed by a later Commission, and the term typho-malarial fever was introduced into our nomenclature of fevers, with the unfortunate results already alluded to.

During the late war there were circumstances which favored to an exceptional degree a combination of the two infections. Large masses of men from the North were exposed in Southern States not only to severe paludal poisoning, but also to typhic infection from the unsanitary conditions incidental to camp life, and there were doubtless good reasons for assuming such a double infection in a certain, perhaps a large, portion of the fever cases. But to apply these observations to fevers developing under the widely different conditions of civil life, and to regard such combined infections as of common occurrence is open to serious objection. Many cases of simple typhoid fever present, during their course, symptoms that bear a certain resemblance to those of malarial fever. So, also, it is contended by writers of large experience in regions where the intenser forms of malarial infections are encountered, malarial fever occasionally assumes an adynamic form, with more or less pronounced enteric symptoms that may be mistaken for those of typhoid fever. In such cases the temperature curve loses its remittent type after a few days, and the fever becomes subcontinuous, with adynamic symptoms. The resemblance to typhoid fever may be increased also by the development of intestinal symptoms, meteorism, diarrhœa, and even hemorrhages. A certain amount of congestion of the alimentary canal, especially of the stomach and upper part of the intestines, is present in most cases of remittent fever, as shown by the frequency of bilious vomiting and epigastric tenderness in this disease. In severer forms patches of inflammation may occur also in the ileum and large intestines, with ulcerations, which usually differ, however, from those of tyophid fever in not being confined to Peyer's patches and the solitary glands. Ulcerations confined to these situations are doubtless to be regarded as more or less pathognomonic of typhoid fever; but it is quite possible that in rare instances malarial infection may produce a type of intestinal ulceration quite indistinguishable from that of typhoid fever. In such cases the true nature of the ulcerations may be shown by the melanæmia and the pigmentation of the liver, spleen, kidneys, and cortex of the brain.

---

[1] Deaths from intermittent fever are very rare in this part of the country, except in persons coming from hot climates, and suffering from the congestive forms of this disease. Even such cases, however, are so uncommon as to be remembered among the curiosities of medical experience. It will scarcely be credited, therefore, that not far from one hundred and fifty deaths from "intermittent fever" are reported to the Board of Health of this city annually This fact indicates a degree of "malarial bias" that I was not prepared to expect.

For comparison I have been compelled to use mortality instead of morbility statistics, because the latter are not available, as few except fatal cases of fevers are reported to the Sanitary Bureau. But since the percentage of mortality is very much less in malarial than in typhoid fever, it is evident that the above mortality statistics do not represent fairly the relative frequency of cases diagnosticated respectively as typhoid fever and malarial fever in this city. Could the facts be obtained, they would show unquestionably that the number of cases diagnosticated and treated in this city as malarial remittent and typho-malarial fever, is greatly in excess of the number of cases diagnosticated and treated as typhoid fever.

The form of malarial fever just described has given rise, as is well known, to much controversy, and many writers doubt its existence independent of typhic infection. Such cases are still regarded by a large part of the profession in our Southern States and in India as typho-malarial fever, but many competent observers in both countries maintain its occurrence as a separate disease. This view is taken by Dr. Squire in the article to which we have already referred. He retains the term typho-malarial fever, but uses it in the sense of a malarial fever with typhoid symptoms, but without typhic infection. Many of our Southern writers prefer the term "malarial continued fever," which has the advantage of recognizing the nature of the disease, while at the same time distinguishing it from the milder and more common remittent form of malarial fever.

The differentiation of typhoid fever from malarial continued fever, especially if the latter be complicated by marked intestinal symptoms, is often very difficult. In this severe form of malarial infection quinine frequently fails to break the fever, so that we cannot rely upon the effects of this drug to guide us. Crops of rose-spots indicate typhoid fever almost with certainty, as they are never seen in simple malarial fever; but this symptom is often absent in typhoid fever, particularly in warm climates. A careful analysis of all the symptoms, with a consideration of surrounding conditions, will usually suffice to establish the diagnosis; but in some cases a differentiation between the two diseases is impossible without a microscopical examination of the blood or alvine discharges.

As a means of differentiating typhoid fever, malarial fever, and acute miliary tuberculosis, such examinations during life are of great value in doubtful cases, although with our present methods only positive results can be regarded as diagnostic. In acute miliary tuberculosis, besides the detection of tubercles in the choroid by ophthalmoscopic examination, tubercle bacilli may be found in the sputa in the pulmonary forms; while in the general forms, without marked pulmonary localization, the bacilli, as Meisels[1] has shown, may be discovered in blood drawn by puncture of the spleen, where the bacilli are often more numerous than in the general circulation. In malarial fever the malarial germ, or pigment granules, may be found in blood drawn from the finger or surface of the body, but with greater certainty in the splenic blood. In typhoid fever examinations for Eberth's bacilli have been less satisfactory; still a number of successful results have been reported. Thus Neuhauss[2] succeeded in nine out of fifteen cases in obtaining characteristic bacilli from blood taken from incisions through the rose-spots of typhoid fever, and in cultivating them upon nutritive gelatine. Inoculations with blood drawn from other parts of the skin remained sterile. He regards the rose-spots as cutaneous emboli of these micro-organisms. On the other hand, Merkel and Goldschmidt[3] repeated these experiments without success. In six cases they failed to find the bacilli in blood taken from the finger, and from rose-spots, and the cultures remained sterile. In three of these cases, however, bacilli were found in the stools, establishing the diagnosis, which had previously been doubtful. Leitz, Fraenkel and Simonds, and Pfeiffer, have also found the bacilli in the stools of typhoid fever, though in a minority of cases. In splenic blood and pulp successful results have been obtained by Hein[4] as well as by Meisels,[5] who states that the bacilli are less numerous in the later stages of the disease, and that distinct differences in their number are noticeable according as the blood is examined during the remissions or during the exacerbations of fever. With constant high temperatures these differences are less marked. He infers from this fact that the bacilli have an ephemeral existence, and that large numbers of them disappear during the exacerbations of fever, as seems to be the case also with the germ of malarial fever.

In examinations for the typhoid bacilli and for the malarial germ, splenic blood is much to be preferred, as it contains these organisms in larger number than the blood of the surface of the body; but whether puncture of the spleen for this purpose, with a thoroughly disinfected needle, is entirely free from danger, should be considered carefully. Seitz regards the operation as hazardous. At an autopsy of a case of typhoid fever he punctured the spleen to obtain blood and pulp, and found, on opening the abdomen, laceration of the capsule and an extravasation of blood into the peritoneal cavity. On the other hand, Dr. Councilman, of Baltimore, in a recent letter to me on this subject writes: "I have punctured the spleen with a carefully disinfected needle twenty-one times without any bad results. Previous to last autumn I have punctured in both typhoid and malarial cases. In one typhoid case the needle broke off short and was left in the organ, and no bad results followed. The needle should be disinfected by boiling. I should not hesitate to put a needle which I knew was pure into any part of the body, save possibly the medulla."

Dr. Councilman's opinion as to the harmlessness of the operation is doubtless correct for the great majority of cases; but I am by no means certain that serious accidents may not arise in exceptional instances. In advanced stages of typhoid and malarial fevers the splenic pulp is frequently much softened, and may be even of a semifluid consistence. In seven out of forty-six cases of typhoid fever Louis found the pulp reduced to a mass of "putrilage," and several cases have been reported in which spontaneous rupture of the spleen has occurred. Marked softening of the splenic pulp to such a degree that the spleen "presents the consistency of a mere bag of blood" has been observed occasionally also in malarial fever.[1] With a tense distention of the capsule under these circumstances, the conditions are similar to those of a hollow viscus with fluid contents, and it is now well known that when the wall of such a viscus is tensely stretched the opening made by puncture, even with a fine needle, sometimes fails to close after withdrawal of the needle, and the fluid contents escape. I have seen one case of fatal peritonitis produced by puncture of the gall-bladder for diagnostic purpose, the autopsy showing a considerable discharge of bile into the peritoneal cavity; and fatal results have been noted also from puncture of the intestines for the relief of meteorism.[2] Diagnostic puncture of the spleen, with proper precautions as to disinfecting of the needle is probably a perfectly safe procedure in the early stages of a febrile process; but in advanced stages the possibility of the accident referred to must be borne in mind.

A word, in conclusion, with regard to a urine test proposed by Professor Ehrlich,[3] of Berlin, in 1882. Dr. C. L. Dana, it will be remembered, brought this subject before this Society three years ago, and I have little to add to what he said on that occasion, except to present my own experience with this test as an aid in the diagnosis of typhoid fever. As the test seems to have been but little used in this country, I append the formulas for its preparation.

The reaction consists in the production of certain colors in the urine (diazor-benzol reaction) by the addition of sulphanilic acid in the presence of nitrous acid, and the alkalinization of the mixture by strong aqua ammoniæ. As the test spoils rapidly, it is better to keep two separate solutions which are to be combined when needed, or to make a fresh preparation when examinations are made only at long intervals. No failure to obtain the reaction can be relied on unless we are certain that the test solution is unspoiled. The two solutions are prepared as follows:

℞. Acidi hydrochlorici (pure).... 1 part.
Aquæ.................... 20 parts.
Sulphanilic acid............ to saturation.
M. Signa—Solution A.
℞. Sodii nitritis.................... 1 part.
Aquæ..................... ... 200 parts.
M. Signa—Solution B.

This solution spoils more readily, and should be renewed more frequently than Solution A.

The test solution is made by adding one part of Solution B, to twenty-five parts of Solution A. Equal parts of the urine and of the test solution are mixed in a test-tube, and then stronger aqua ammoniæ is added freely to alkalinize the mixture. In normal urine the addition of the ammonia merely deepens the color, or develops a light reddish tinge, and the deposit of phosphates, after twelve to twenty-four hours, retains its grayish color. In urine presenting the characteristic reaction, addition of ammonia produces an intense scarlet, carmine, reddish orange, or even purplish color, and the phosphatic deposit is colored billiard green, violet, or greenish black, especially in its upper portion, as the layers last deposited carry down with them more of the pigment.

During the past five months Dr. Vaughan, of the house-staff of St. Luke's Hospital, at my request, has used this test in all urinary examinations, no results being recorded as positive which did not present the above-mentioned characteristics. Over seven hundred examinations were made in three hundred and seventy-five different patients. A characteristic reaction was found in all the cases of typhoid fever, fifteen in number; and the intensity of the reaction usually corresponded with the severity of the disease in its several stages. The reactions were always more marked, as Ehrlich has noted, in the relapses than in the primary attack. Well marked reactions were found, also, in almost all advanced cases of phthisis, even in the absence of fever: in three out of nine cases of lobar pneumonia, these three being fatal cases and in an adynamic condition at the time of examination; in two cases of empyema; in two cases of diffused carcinoma of the abdominal viscera; in one out of two cases of scarlet fever, and in one case of ulcerative proctitis.

These results correspond, in a limited way, with those obtained by Ehrlich in his far larger number of examinations—over seven thousand. He found the reaction occasionally in afebrile condition, such as advanced heart-defects, chronic hepatitis, carcinoma, especially of the pylorus, in the later stages of leucæmia, in senile marasmus, in severe malarial cachexia, cold abscesses, phosphorus-poisoning, and acute gastric catarrh. The febrile conditions presenting the reaction he classifies under three groups: 1. Rheumatism, meningitis, and erysipelas, in which it is usually absent; 2, pneumonia, scarlet fever, and diphtheria, in which it is encountered more frequently; and 3, typhoid fever and measles, which give the reaction almost invariably. In abortive and very mild cases of typhoid fever he has observed its occasional absence. Two instances of this kind have fallen under my observation. In the first case—one of mild typhoid fever without diarrhœa or meteorism, but with typical successive crops of lenticular spots, and aborting on the sixteenth day—no reactions were obtained throughout the attack. In the second case, which was seen first on the twelfth day, no reaction was found on that day, but on the day following a slight but characteristic reaction was obtained. After this time the reaction was invariably absent. This case also was a mild one without diarrhœa, but presented a typical roseola.

In typhoid fever this reaction is found usually as early as from the third to the sixth day, and until just before defervescence takes place. During the course of the attack the reaction sometimes disappears on the development of some severe complication, such as pneumonia, or in great prostration from any cause; but with these exceptions the absence of the reaction, or its feebler manifestation, after pronounced reactions have been obtained, usually indicate the approach of defervescence.

As a diagnostic test for typhoid fever this urinary reaction has little value except from a negative standpoint; but, even with this estimation of it, I regard it as a valuable addition to our means of differential diagnosis. During the first week of typhoid fever—the trying period for diagnosis—it is of little assistance, but after this time the absence of the reaction renders the existence of typhoid fever very doubtful. At St. Luke's Hospital during the past winter, in several obscure cases admitted with a diagnosis of typhoid fever and presenting many of its symptoms, a failure to obtain the reaction has enabled us to exclude this affection, the subsequent course of the attack revealing some other disease. This negative value, it seems to me, is far more important than any positive indication from the presence of the reaction, since the latter is found in so many other febrile affections.

Whether Ehrlich's test has any value in the differential diagnosis of typhoid and malarial fevers I am not prepared to say. The reaction has been absent in all the cases of intermittent fever in which I have tried it, and also in the only cases of malarial remittent—two in number and both from the South—which I have seen during the past year. Ehrlich mentions the occasional presence of the reaction in severe malarial cachexia, but makes no reference to the application of the test in malarial remittent fever. So far as I am aware this point has not been investigated by European observers, and it is to be hoped that this deficiency will be supplied by observations in our Southern States where ample material is always at hand.

In the application of this test the following points are specially important: 1. The test solution should be fresh; 2. a greenish or violet color of the phosphatic deposit, especially of its upper layers, is more significant than the color of the urine produced by the addition of ammonia; and 3, as regards typhoid fever, the absence of the reaction has greater diagnostic value than its presence.

ENTEROSTOMY FOR ACUTE INTESTINAL OBSTRUCTION.

By B. FARQUHAR CURTIS, M.D.,

ATTENDING SURGEON TO ST. LUKE'S HOSPITAL, NEW YORK.

While studying the results of laparotomy for acute intestinal obstruction, in the preparation of a recent paper (*Annals of Surgery*, May, 1888, p. 329), I could find no statistics of the operation of enterostomy performed for that condition, except the figures of Treves, who gives a rate of mortality of 67.2 per cent. in sixty-one cases—a percentage which appeared to me much too high. A tolerably thorough search through the literature has revealed the fact that the operation is less often performed at the present time than laparotomy, or, at least, less often reported, for I have been able to gather only sixty-two cases, against the three hundred and twenty-eight cases of laparotomy which formed the basis of my first study.

It should be stated in the beginning that, by enterostomy is understood the operation of forming an artificial anus in any portion of the intestinal canal, including both "enterotomy" and colotomy. The cases have been collected within the same limits as the series of laparotomies, using only the acute cases with sufficiently complete histories, from 1873 to the end of 1887. It is often difficult to draw the line between the acute and chronic cases, and in some instances it has not been easy to determine whether certain operations, in which considerable exploration of the peritoneal cavity was made, should be classified as enterostomies or laparotomies. But as the same hand has collected both series, it is hoped that the errors will balance, or, at least, give no undue favor to either side.

The results in this series of sixty-two cases of enterostomy, performed for acute intestinal obstruction, were as follows: Forty-six cases (seventy-two per cent.) were relieved by the operation, six cases were not relieved (in three the fistula was established below the obstructed point), and in the other ten cases there is no definite statement whether relief was obtained or not, several of them having died within a very few hours.

Thirty-two cases recovered. In nineteen of these cases the fæces resumed their natural passage per anum, generally within a few days—three cases within twenty-four hours, nine more during the first week, and four more during the second week. The longest interval before the resumption of passages per anum in these cases was ten weeks. To these should be added two of the fatal cases, in which the passages per anum were resumed four, and fourteen days, respectively, after the operation. The fistula closed spontaneously in seven cases, and in six others it was closed by operation. It probably closed, or at least contracted to inconsiderable dimensions, in many others who were lost sight of before that result was attained.

Thirty cases died, a mortality of only 48.3 per cent. Stating these facts in tabular form we have:

Relieved by the operation............	46 cases,	= 72 per cent.	
Not relieved........................	6 "		
Recovered...........................	32 "	= 51.7 "	
Passages per anum resumed in	19 "	= 60 "	of recoveries.
Died	30 "	= 48.3 per cent.	

These results were so remarkable that I hesitated to adopt them. A certain glamour surrounds the laparotomist, and a surgeon might be ready to publish an unsuccessful case of laparotomy, who would feel that there was but little honor to be won in publishing an unsuccessful enterostomy. But the last fifteen cases in the series happen to furnish the results of the experience of two surgeons, Schede and Fuhr, and presumably contain all their failures as well as their successes, and an analysis of these cases yields results even more favorable than that of the entire series. Their record reads: Total, 15; relieved, 14; unrelieved, 1; died, 4; recovered, 11, including as a recovery one case which died of delirium tremens ten days after the operation, and in which natural passage of the fæces took place on the fifth day. Of the eleven cases which recovered, the passages per anum were resumed in seven, including the case just mentioned. The fistula closed spontaneously in two cases, and in four it was closed by plastic operation. Among the fatal cases is also a case in which natural passages took place in fourteen days, death being due to an attack of erysipelas two months after the fistula was formed.

Another aspect of this subject is the condition of the patients who recovered at the time of the operation. This is given in twenty-one of the thirty-two cases, being fair in six, bad in eight, and very poor in seven cases. In many cases, in fact, it was the bad condition of the patient which led to the choice of enterostomy instead of laparotomy. These facts compel us to accept these favorable results for enterostomy, however bad the comparison may be for laparotomy, with its mortality of 68.9 per cent.

That there may be no dispute as to classification, the details of all the cases in which there could possibly be room for doubt (four cases ranked as recoveries, and two as deaths) are given below.

Case LI.—Male, aged forty-five years. Obstruction for six days. In very bad condition. Enterostomy, left side. Fæces per anum in five days. Was recovering, when delirium tremens set in. Died on tenth day. Considered as a recovery from both obstruction and operation.

Case XXXI.—Male, aged seventy-six years. Obstruction for fifteen days. Bad condition. Enterostomy, right groin, relieved. Mental disease, refused food, died in three weeks. Autopsy—volvulus of small intestine below the fistula, gut not gangrenous. Considered as a recovery.

Cases LIII. and LXII. died of the results of overdistention of the bowel by the accumulation of material between the fistula and the point of obstruction below, but after such a long interval that they may fairly be classed as recoveries. The details of these cases will be given below.

Case XII.—Male, aged forty-three years. Obstruction for six days. (Attacks ten and twenty days previously, relieved by enema, and by the introduction of the hand into the rectum.) A tumor felt between the bladder and the rectum. Left lumbar colotomy. Was relieved, but continued to lose strength, and thirteen days later something was felt by the patient to give way inside, death following within an hour. Here probably the operation relieved the obstruction, but progress of a cancerous tumor continued and resulted in perforation of the bowel. But as it is not certain that this was not a case of volvulus or internal strangulation with gangrene and perforation, it is reckoned among the fatal cases.

Case XLVIII.—Female, aged fifty-eight years. Obstruction four days. (Three weeks previously herniotomy was performed for right femoral hernia, and a fecal fistula formed in the wound, and erysipelas attacked it.) Very bad condition. Enterostomy, left groin, relieved. The other fistula began to discharge again in seven days, and fæces passed per anum in fourteen days. The right fistula closed spontaneously, and the left was closing when erysipelas started again from it, and caused death two months after the operation. Autopsy revealed adhesions as the cause of the obstruction. This case is considered a fatal one, because of the septic infection of the wound, one of the dangers of the operation, even as late as it took place in this patient.

An analysis of the causes of death is necessary, espe cially in comparing the operation with laparotomy, and they are given in the following table:

Causes of Death after Enterostomy for Acute Intestinal Obstruction.

	Cases.	
Sepsis from the wound	5	
Failure to reach distended gut	3	
Gangrene of the gut subsequent to the operation	4	
Shock	4	
Total due to the operation, or its failure		16
Bad condition of the patient	7	
Heart failure	1	
Perforation of gut on thirteenth day. (Cancer?)	1	
Gangrene of the gut existing at time of operation	1	
Extensive adhesions, infant, malnutrition	1	
Total, independent of operation		11
Cause unknown		3
Total		30

In order to compare these results with those of laparotomy I quote the table from the article referred to, with some variation in arrangement.

Causes of Death after Laparotomy for Acute Intestinal Obstruction.

	Cases.	
Sepsis not due to gangrene of the bowel	17	
Prolonged operation	3	
Shock	13	
Cause of obstruction overlooked, or not found	19	
Total due to the operation, or its failure		52
Poor condition of the patient	101	
Complications (peritonitis, gangrene, various)	41	
Cause of obstruction irremediable	9	
Total, independent of the operation		151
Cause unknown, details wanting		23
Total		226

It will be seen at once that a larger proportion of deaths are set down as due to the operation in enterostomy than in laparotomy, but the reason is simply that the great majority of these patients are in such a miserable condition that the mere shock of an operation like laparotomy causes death, while enterostomy is so much less severe that its performance is seldom immediately fatal. Hence not enough patients survived the first danger of laparotomy—the shock—to enable us to form an idea of how many would have perished of peritonitis and other dangers of the operation. Certainly the proportion of these later accidents would have been much greater after laparotomy than after the relatively simple operation of enterostomy.

One very remarkable fact which appears in this study of the causes of death is that in only three cases was death occasioned by gangrene of the gut taking place after the operation. This danger at once occurs to the mind as the chief objection to enterostomy as compared with laparotomy, for by the latter operation the surgeon is enabled to remove the cause of the obstruction, while in the former it is left untouched. It is natural to suppose that a failure to cut the band, untwist the volvulus, or reduce the intussusception would be followed by gangrene of the gut and certain death, even if the bowel above were relieved of its contents by an artificial anus. But, as we have seen, the facts do not support this belief. More than that, there are some cases at our disposal which prove that relief of the pressure from behind will actually remove the cause of constriction, or render it so harmless that the fæces can even resume their normal passage. We give these cases in detail.

Case XLV.—Female, aged fifty-two years. Obstruction for ten days. Enterostomy, right groin, cæcum opened. Exploration through the wound showed existence of an intussusception of the ascending colon. Recovered.

Case XXXVII.—Male. Enterostomy, right groin. In two weeks twenty centimetres of gangrenous gut was expelled per anum. Recovered. In this case the enterostomy gave time for spontaneous cure.

Case XXXI.—Male, aged seventy-six years. Obstruction for fifteen days. Bad condition. Enterostomy, right groin. Relieved, no passage per anum. Demented, refused food, died of inanition in three weeks. Autopsy: Volvulus of small intestine below the fistula, without gangrene of the gut.

Case XLVIII.—The details of this case have been given above. Obstruction was caused by adhesions, and relieved by enterostomy.

Case LV.—Male, aged forty-two years. Obstruction for four days. Poor condition. Enterostomy, right iliac, small intestine opened. Fæces per anum in five days. Six weeks later, laparotomy, adhesions in pelvis found and freed, and artificial anus closed. Recovered.

Case LVIII.—Female, aged thirty-eight years. Obstruction for three days. Femoral hernia. Herniotomy, no constriction in sac; incision extended upward, and cæcum opened. Fæces per anum in two weeks. Four weeks later laparotomy to close the fistula; a band found attached to the small intestine and the cæcum, supposed cause of obstruction, divided. Recovered.

Case XLIII.—Female, aged fifty-two years. Obstruction for six days. Enterostomy, left groin. A few hours later a large mass of fig-seeds passed per anum and there was no further trouble. The fistula contracted rapidly.

To these cases we may add a similar one observed by v. Wahl (*St. Petersburg med. Wochenschr.*, 1886, 183).

Female, aged fifty-four years. Obstruction after reduction of umbilical hernia. On sixth day a fistula was made at the umbilicus without relief. On the twelfth day, laparotomy, median incision above the umbilicus; no cause of obstruction found; artificial anus made in the incision. Fæces per anum in three days. Recovered. Fistula permanent. v. Wahl considers this a case of internal incarceration.

These cases show that intussusception, volvulus, adhesions, bands, impaction of foreign bodies, and even internal incarceration, can be relieved, or at least rendered harmless, by simply removing the pressure from behind, as is done by opening the distended bowel. In some cases, indeed, this would seem probable enough *à priori.* The adhesion, band, or even internal incarceration, has in most cases existed for some time, and the intestine has maintained its passage by increased force of peristalsis. But although the parts remain nearly in the same relative position, some sudden undue distention of the gut causes the latter to be so bent or constricted that it can no longer overcome the obstruction in the path of its contents. The longer the obstruction lasts, the greater the pressure and the tighter the constriction. Remove the pressure entirely, and it becomes easy for affairs to return to their previous condition, the gut having its former power of overcoming the obstruction restored to it. Even when a loop of intestine has slipped into an opening, or under a band, for the first time, it is not at all improbable that the relief of pressure will enable it to escape again. At all events, our cases prove that there is some hope that it may do so, and that there is a "fighting chance" in enterostomy.

The operation of enterostomy may fail in three ways: First, the fistula may be made below the constricted point, especially when there is more than one obstruction, or it may be situated in the distended and doubly occluded loop which has undergone a volvulus, or been strangulated through an abnormal aperture; secondly, the fistula may be properly placed, and yet be inefficient because the bowel refuses to contract, being paralyzed by over-distention or by peritonitis; thirdly, the fistula may act well, but death may ensue by continuance of the constriction and gangrene of the included gut. We have just discussed the last cause of failure. Of the second there are two instances in our series, Cases XVI. and XVII., besides others in which the fistula acted, but not until some time after it was formed. As to the first cause of failure, in only three cases was the fistula made below the point of obstruction, a percentage of 4.8, which compares very favorably with the record of failures in laparotomy, for in nineteen cases out of three hundred and twenty-eight of the latter, 5.8 per cent., death resulted because the obstruction was overlooked or could not be found.

But besides the liability to death at the time of operation, from the original obstruction, from failure of the operation, or from some of the dangers inherent in it, there remains a source of danger to the bearer of a permanent fistula with a permanent constriction of the bowel farther down, in the possibility of accumulation of fecal matter between the two. This is well illustrated by the following cases:

CASE LIII.—Female, aged forty-seven years. Obstruction for thirteen days. Enterostomy, left groin. Recovered. No passages per anum. Two years later she died with an enormously distended abdomen, although the fistula continued to act. Autopsy showed a cicatricial stricture of the sigmoid flexure, with a great collection of fecal matter between it and the fistula above, and this had caused death by its pressure upon all the viscera, and by fecal absorption.

CASE LXII.—Male, aged eighty years, but robust. Obstruction for fourteen days, good condition. Colotomy, cæcum opened. Recovered. Several months later he died of rupture of the intestine where the wall was perfectly healthy, the whole large intestine being very much distended by fæces collected below the fistula and above the obstruction, which was a cancer situated in the sigmoid flexure.

To avoid such consequences as these, it has been proposed to construct the artificial anus in such a way as to form a spur, and prevent the passage of any fecal matter beyond. But in cases of acute obstruction this practice would certainly be unjustifiable, for we should then lose the advantage of the large percentage of cases which may hope to recover with normal passage for the fæces. This modification of the operation should be confined to cases in which a positive diagnosis of cancer or stricture is possible, and fortunately this is generally not difficult. In all cases of acute obstruction the intestine should be simply sutured in the wound, in such a way as to avoid the formation of a spur.

With regard to this return of the fæces to their natural passage, it must be noted that, even after laparotomy, this ideal result cannot always be obtained. From Table IV. of the paper already quoted, it will be seen that in one hundred and two cases which recovered after laparotomy, in only eighty-one could the natural channel of the fæces be preserved, giving a rate of seventy-nine per cent., which is not so very much better than the sixty per cent. which we have found for enterostomy. This result is less surprising when it is remembered how late these cases are brought to the surgeon, and how often extensive adhesions, gangrene of the bowel, or the feeble state of the patient (demanding a rapid termination of the operation) compel the surgeon to make an artificial anus.

For the sake of completeness, the following facts may be recorded before closing: The fistula was made in the right groin twenty-eight times, in the left, twenty-one times. The small intestine was opened in thirteen cases, the sigmoid flexure in six, and the cæcum in nine, the rest not being specified. Lumbar colotomy was performed in seven cases.

The variety of obstruction was determined (mostly by autopsy in fatal cases) to be—intussusception in six cases, four died; volvulus in three cases, two died; adhesions in five cases, four died; bands and diverticula in four cases, three died; internal incarceration in one case, fatal; stricture, five cases, four died; tumors of the bowel, ten cases, six died; foreign bodies, two cases, none died; compression by pelvic tumor, one case, recovered; peri-uterine hæmatocele, one case, recovered; no cause of obstruction found, two cases (peritonitis, paralysis of intestine), both died. In the other twenty-one cases, with three deaths, the cause was not ascertained. The relative mortality for these various forms of obstruction is unimportant, for the numbers are too small, but it is remarkable that, out of ten cases of tumor of the intestine, and six cases of stricture, which are supposed to be the most promising varieties of obstruction for this mode of treatment, there were ten deaths; while, on the other hand, two cases of intussusception recovered out of six, and one case out of four of volvulus.

In conclusion, we may compare the two operations for the relief of acute intestinal obstruction as follows: 1. The mortality for laparotomy is 68.9 per cent. The mortality for enterostomy is 48.7 per cent. 2. In enterostomy 4.8 per cent. of the sixty-two cases died because the operation did not relieve the constriction; but even in laparotomy 5.8 per cent. of the three hundred and twenty-eight cases died from the same cause. 3. Enterostomy restores the natural passage for the fæces in sixty per cent. of the cases which recovered; while even laparotomy preserves it in only seventy-nine per cent. of the recoveries. 4. Laparotomy is therefore so very little better than enterostomy, that, in consideration of its greatly increased risk, it is indicated only when the patient's condition is so good that he can bear the shock, and when the intestines are not so greatly distended as to offer a serious obstacle to a thorough exploration of the abdomen. 5. Under all other circumstances enterostomy should be performed, and if necessary this can be done without an anæsthetic. Laparotomy may be resorted to later, to remove the cause of obstruction and to close the artificial anus. 6. Whichever operation may be chosen, it is necessary to operate early, for every delay greatly increases the risk of failure.

MEDICAL ADVERTISING IN GERMANY.—At a little village in Germany, recently, a crier went through the streets proclaiming that a certain physician in the place would give medical advice to all comers for the reasonable sum of 60 pfennige (15 cents). Two hours later the same crier passed through the town announcing that the other doctor of the village was prepared to give his services to the sick for 50 pfennige (12 cents) a visit.

PROGRESSIVE MUSCULAR ATROPHY, WITH ANÆSTHESIA.[1]

By J. A. BOOTH, M.D.,

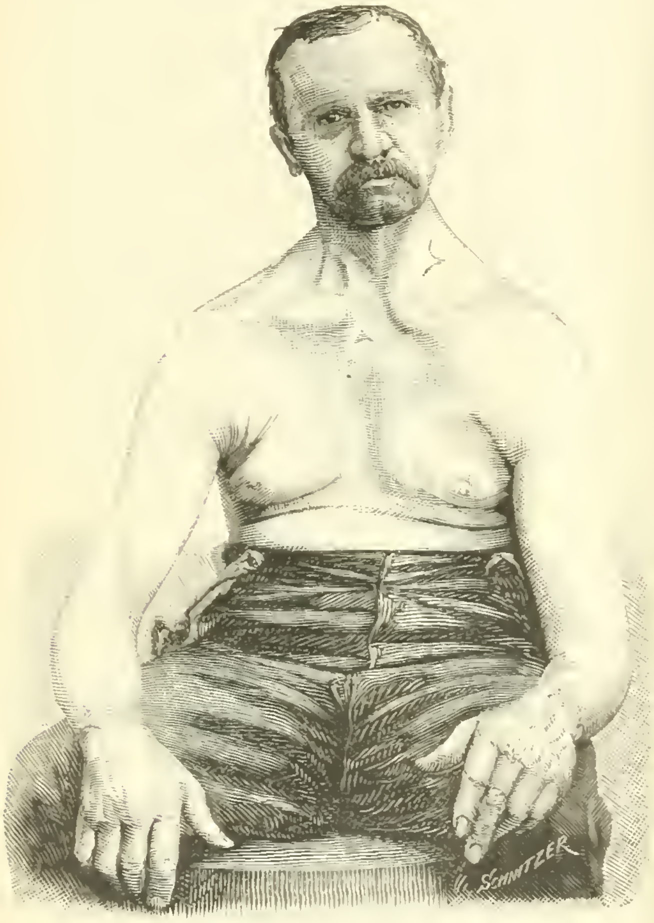
ASSISTANT PHYSICIAN TO THE NERVOUS DEPARTMENT OF THE MANHATTAN EYE AND EAR HOSPITAL.

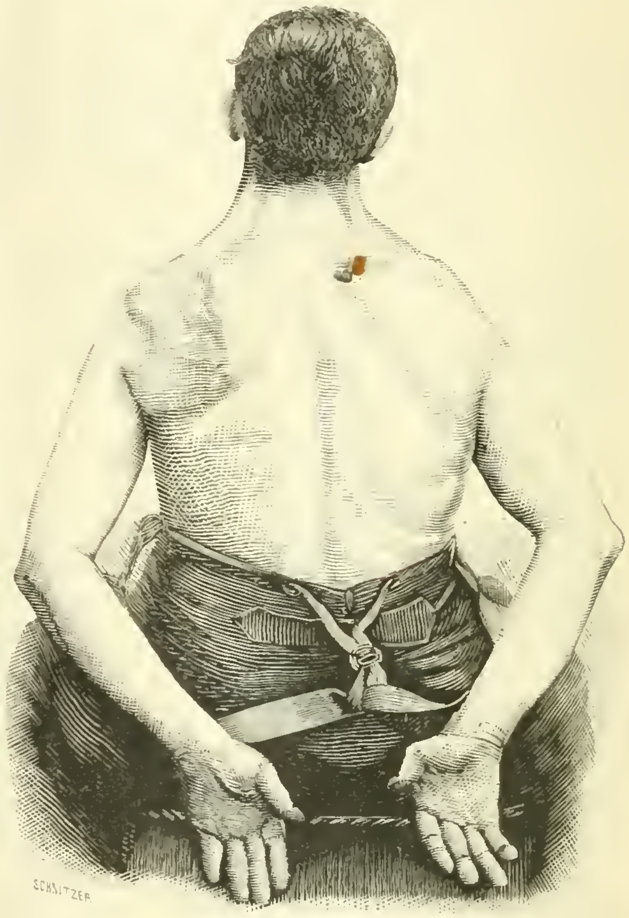
F. K——, aged forty-two, married; shoemaker; German.

Family history good; no history of any nervous or tubercular disease, alcoholism, or syphilis, nor has anyone in the family had any similar disease.

Personal history.—Was always strong and healthy. He never indulged in excesses of any kind, and never had any venereal disease. He never received a blow or fall, nor is there any history of exposure to wet and cold. Been married eighteen years; has two children, the older, a girl of five years, has never walked.

Present disease.—The first symptoms were noticed about eight years ago, from October, 1878, to January, 1879, and came on gradually; they were general debility, a worn-out, tired feeling, and dizziness. He was inclined to lie down most of the time, but never felt rested. About the same time he observed weakness in arms and hands, with inability to use his awl so well. No change was noticeable in the appearance of the shoulders, arms, or hands at this time.





Seven years ago (January, 1879) the voice became husky and changed. He has spoken in a harsh, unequal tone since. Six months later (June, 1879), sensations of cold and numbness appeared in left shoulder, gradually extending to neck, arm, and hand of same side. This sense of numbness was especially severe and troublesome on left side of neck, so that he resorted to very hot applications for relief. After the removal of a poultice, it was discovered that his neck had been badly burned, though he had not experienced any sense of pain. About September, 1879, a decrease in size and a difference in the shape of the shoulders was noticed, the left being more prominent than the right. This atrophy of muscles, first noticed in the deltoids, slowly progressed, involving the trapezii and scapular muscles, and the interossei of the hands; and still later, the latissimus dorsi, the pectoral muscles and extensors of arms.

In October, 1855, a painless ulcer formed in helix of left ear, which went on to perforation. Some time elapsed before this healed. During the last three years he has been closely observed by me, and the only new symptoms that have developed are an increase in the muscular weakness, a slight difficulty in swallowing, and a sense of heaviness in the tongue. He has also noticed lately that his eyesight is not so good. He is also frequently dizzy.

Present condition.—The patient is a man of medium size—weight, one hundred and fifty-five pounds. There is a marked sinking of both shoulders. His voice is harsh, impure, and unequal in tone. On the left side of neck there is a cheloid scar, the result of a burn. On both hands are noticed several scars and abrasions. He notices that slight wounds and abrasions of the skin heal very slowly and imperfectly, remaining for some time as open sores, and, morever, that these cause no pain.

Nervous system; motor functions.—He shows no ataxia in gait or on standing. There is marked muscular weakness in upper extremities. The movements of the upper extremities are imperfect and limited. The grasping power of both hands, as measured by the dynamometer, is diminished; R., 30.32; L., 28.26. The little and ring fingers of right hand are slightly flexed, and their movements limited. All the interossei are wasted, especially third and fourth of right hand. The muscles attaching the upper extremities to the trunk are atrophied. The atrophy is more marked in some muscles and in some parts of muscles than in others; the lower part of the trapezius is much more affected than the upper; the upper part of the pectoral muscles more than the lower. The left cheek feels thinner and less firm than the right. There is no appreciable difference between the two sides of the tongue, though the patient states that the left side feels different from the right. When the tongue is protruded to its fullest extent, there is a slight deviation to the right. There is a marked paralysis of the palate, it and the uvula being sharply drawn to the right. An examination of the larynx reveals a paralysis of left vocal cord. An examination of the patient's throat was also made by Dr. Andrew H. Smith, and he reports as follows:

---

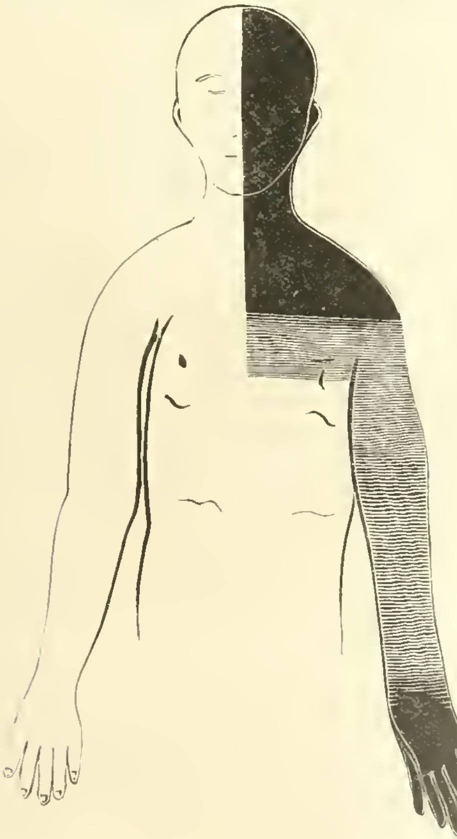
[1] Read before the Neurological Society, June 5, 1888.

"Patient has a high, stridulous voice; no difficulty in respiration or deglutition. Examination shows complete paralysis of the left superior constrictor of the pharynx, and of the left palato-pharyngeus. There is also paresis of the adductors of the left vocal chord. The paralysis of the superior constrictor results in a rotation of the mucous membrane of the fauces toward the right with every vocal effort. This case would seem to indicate that the superior constrictors are energized with every effort at speech, but owing to the perfect balance between them, no visible movement results. The laming of one, however, renders the action of the other immediately apparent."

The mechanical irritability of the atrophied muscles is increased.

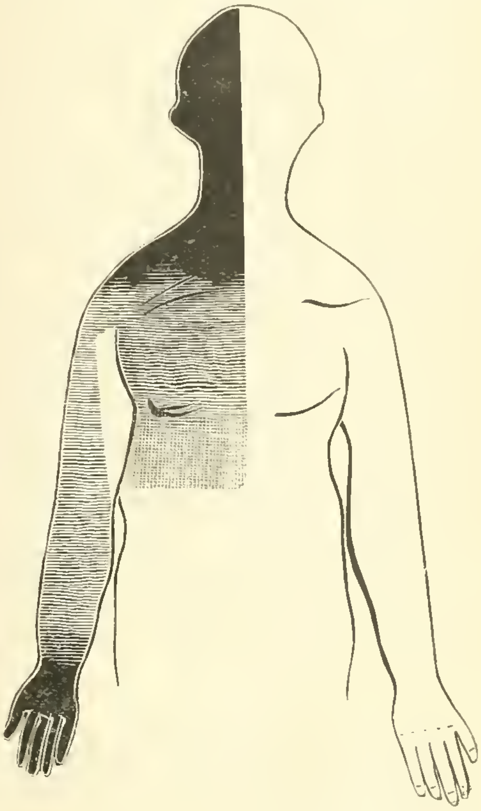
Electrical irritability.—Very marked fibrillary twitchings frequently occur in the atrophied muscles. There is a general reduction in the strength of the contraction produced both with the faradic and voltaic currents. The inferior segment of the trapezius fails to contract with the strongest faradic current. The only muscles which give a true reaction of degeneration are the third and fourth interossei of the right hand.

Reflexes.—The patella tendon reflexes are exaggerated; organic reflexes are natural. No clonus. Muscular sense not impaired. Nothing abnormal found in lower extremities.



Deep shading = complete anæsthesia. Light shading = slight anæsthesia.

Sensory functions.—He complains of feeling cold, and states that left side of face, head, and neck are numb, also both hands. The skin of left face, arm, shoulder, forearm, and hand; also left side of trunk and neck, as far forward and backward as the median line, and as far downward as the fourth rib in front and ninth rib behind, is anæsthetic—a region corresponding to the distribution of the cervical and brachial plexuses of the intercostal and fifth cranial nerve. This region of insensibility is somewhat ill-defined on the trunk behind, but on the face its limits are sharply marked. One-half of the mucous membrane of the tongue, mouth, and palate of the same side are insensitive. On the right side there is no anæsthesia of face, head, or neck. But on dorsum of hand, over anterior and lateral aspects of arm, sensation is not natural. There is no response to metals.



Deep shading = complete anæsthesia. Light shading = slight anæsthesia.

There is marked analgesia, which occupies the same distribution as the anæsthesia.

Sensibility to temperature.—There is a complete loss of temperature sense over entire circumference of hands and left side of neck; partial loss over both deltoids, anterior and lateral aspects of arms and forearms, and on left side of face. Tests used were sponge, dipped first in hot, then in cold water, and test-tubes containing hot and cold water. Warm objects seem cold. After prolonged contact the test-tube of hot water was frequently recognized.

Sight.—There has been no trouble referable to the eyes until lately. He has now to look at an object some little time before recognition is complete. No diplopia. No change in the visual field of either eye. Optic nerves normal. Taste and smell are natural. Hearing not impaired.

Remarks.—There are present in this case three sets of symptoms. 1. The muscular atrophy. 2. The bulbar symptoms. 3. The hemianæsthesia and analgesia, the characteristic slow wasting, the loss of power, and the result obtained from the electrical examination, decide the case to be one of progressive muscular atrophy, with the usual changes in the spinal cord—a slow degeneration of the ganglion cells of the anterior cornua, accompanied by a similar degeneration in the motor-nerve fibres which spring from the cells.

It not infrequently happens that the degenerative process, which previously had involved the large nerve-cells of the anterior cornua, extends upward and involves the motor nerve nuclei of the pons and medulla. And thus, as in the case before us, bulbar symptoms are added to those of the original affection, viz., paralysis of the palate, pharynx, and left vocal cord, paresis of tongue, and dysphagia.

Regarding the sensory disturbance, any marked loss of sensation is certainly not one of the changes we expect to find in cases of progressive muscular atrophy. Therefore its presence in this case, so well marked and limited, justifies me in considering the hemianæsthesia as a separate complication and due to a lesion in the sensory tract.

Hemianæsthesia presents itself with two different degrees of completeness: 1, cerebral hemianæsthesia; 2, mesocephalic hemianæsthesia.

1. The first, or cerebral form, is the most complete. The special senses are generally involved. It is due to a lesion of the posterior third of the hinder segment of the internal capsule. The anæsthesia may be complete or incomplete, depending on the extent of the lesion.

2. The second, or mesocephalic form, is less complete, and may be produced by lesion or disease in the upper or outer layers of either the cerebral peduncle or pons Varolii. The special senses of smell and sight are not implicated, those of taste and hearing are sometimes lost on the side opposite the lesion.

Conclusions.—The lesion is evidently in some part of the sensory tract, from the following symptoms: Left hemianæsthesia, including loss of sensation of the left half of mouth and tongue; the cutaneous and muscular analgesia and thermo-anæsthesia; loss of pain to strong faradic currents; increased reflexes; attacks of giddiness. The case, then, is one of progressive muscular atrophy, complicated by a secondary lesion either in the internal capsule, peduncle, or pons Varolii of the right side. From the history, and as there is no involvement of the special senses, I am inclined to doubt the presence of a capsular lesion here; but conclude that the hemianæsthesia is of the mesocephalic form, due to a tumor in the upper and outer layers of the pons Varolii or peduncle on the right side.

323 West Fifty-Seventh Street.

A CONTRIBUTION TO THE SURGICAL TREATMENT OF MEMBRANOUS OPACITIES IN THE VITREOUS.[1]

By CHARLES STEDMAN BULL, M.D.,

SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY; CONSULTING OPHTHALMIC SURGEON TO ST. LUKE'S HOSPITAL; TO THE NURSERY AND CHILD'S HOSPITAL; AND TO ST. MARY'S HOSPITAL FOR CHILDREN.

PATHOLOGY teaches us that membranous and cord-like opacities in the vitreous humor are not usually freely movable or floating, owing to the continuity of the original septa, which is more or less completely preserved, and to the consistency of the intercellular substance of the vitreous humor contained within these septa. When, however, the processes of retrogressive metamorphosis and degeneration set in, and the intercellular substance becomes fluid, then these membranous opacities may become freely movable, unless they have formed adhesions to the retina, choroid, or optic nerve; and even then they may often be seen to wave and flutter with every motion of the eyeball. These membranes, no matter how delicate and cobweb-like they may be, resist all internal medication or local applications, even though persisted in for a long time, and such are the vitreous opacities which seem suitable for operation. Von Graefe was the first to suggest the possible advantage of surgical interference in such cases, and he gives in detail the history of a case of a young woman, aged nineteen, in whose left eye a moderately thick membrane extended all across the posterior part of the vitreous. Vision in this eye was reduced to counting fingers at eighteen inches, and the patient could read some words of Jaeger No. 20 with spherical $+\frac{1}{6}$. Von Graefe rotated the eyeball strongly inward, and then plunged a keratonyxis needle through the sclera, between the external and inferior recti, just in front of the equatorial region, parallel to the plane of the iris and behind the lens, and divided the membrane in several places from before backward. In a few days the patient could read Jaeger No. 8 with spherical $+\frac{1}{6}$, and three weeks later she could read Jaeger No. 3 with the naked eye. The ophthalmoscope showed a retraction of the membrane from the centre toward the periphery, and a subsequent absorption of its remains. Ten months after the operation not the slightest trace of the opacity could be discovered in the vitreous, eccentric vision was perfectly normal, and central vision was almost normal.[1]

In the experience of the writer this operation has proved positively useful in some cases. There are some opacities of the vitreous, such as are seen after hemorrhages or inflammatory processes in the choroid, which are capable of undergoing retrogressive metamorphosis, and disappear wholly or in part. But we often meet with membranous opacities which resist all treatment, and not only materially affect the vision, but become still more dangerous through their traction on the retina at their points of adhesion. If we succeed in dividing such membranes we not only gain a direct optical effect and improve the vision, but may also start up an absorptive process which may produce further contraction, and also, by reducing the tension in the membrane, lessen the danger to the retina. If the cornea and lens be transparent, the position of these membranes may be located with tolerable accuracy. When in a choroidal process the infiltration encroaches on the region of the papilla, the opacity in the vitreous is almost certain to occur in its posterior part, in the form of thread, or patches, or membranes, which are often directly connected with the optic papilla by adhesions to the sheath of the central vessels. On the other hand, the farther forward the choroidal infiltration occurs, and the nearer to the ciliary processes, the more anterior are the opacities in the vitreous likely to be. Other things being equal, the posterior opacities are more easily reached by the needle or knife in the proposed operation, the less the danger of injuring the lens, and the more favorable are the results likely to be.[2]

The writer has done this operation in seventeen cases of chronic membranous opacities in the vitreous, and presents the histories of these cases, with the results obtained, to the members of the Society for their consideration. In some of the cases the ordinary discission or keratonyxis needle was employed; in others a broader needle with a double cutting edge; while in still others, where the membrane appeared to be tough and thick, a very slender cataract knife was the instrument selected. Cocaine was employed in all cases. Wherever the peculiarities of the case admitted, the point selected for the puncture was just in front of the equator of the eyeball, and just below the lower border of the external rectus muscle. In a few cases the puncture was made on the nasal side of the eyeball, just below the lower margin of the internal rectus muscle. The operation is a very brief one, and where possible was preceded and followed by a rapid ophthalmoscopic examination. There seems to be no danger of any loss of vitreous through the minute puncture made in the sclera, and almost as little probability of any annoying or disturbing hemorrhage. Care should be taken to make the puncture always posterior to the ciliary processes, and to avoid any undue pressure on the eyeball by the forceps which are used in rotating the eye inward or outward as the case may be. Little or no reaction follows, save in exceptional cases, and a protective bandage is needed for only two or three days.

CASE I.—Selah M——, aged forty-five; first seen October 12, 1885. Patient has always been myopic, but has never worn glasses. Eighteen months before, the left eye had become inflamed without any apparent cause, though he had been rheumatic for years. The attack was accompanied by some pain and marked loss of vision, and the inflammatory symptoms did not subside until nearly four months had elapsed. Since then there has been no relapse, and vision has somewhat improved, but is still extremely defective.

---

[1] Read before the American Ophthalmological Society, at its Twenty-Fourth Annual Meeting, July 18, 1888.

[1] See Archiv. für Ophthalmologie, IX., 2, page 102, 1863.

[2] See Bergmeister, Archiv für Ophthalmologie, XX., 2, page 95, 1874.

Present condition.—R. E., V = $\frac{20}{100}$, with cyl. D 2.50, axis 90° = $\frac{20}{30}$ + ; media clear ; fundus normal except a small conus on temporal side of disc. L. E., V = $\frac{3}{200}$, unimproved ; cornea clear, iris normal in color and reaction, lens transparent except for some faint striæ at the periphery. Under a dilated pupil there is seen a broad, thin, membranous opacity, running from the nasal margin of the optic disc downward, forward, and outward to the lens ; both ends fixed, and the membrane becoming broader as it neared the lens. The rest of the vitreous was apparently clear, but the course of the membrane covered both the disc and the region of the macula. There were traces of an old choroiditis, marked by patches of atrophy, some of them surrounded by a zone of pigment. A four per cent. solution of cocaine was instilled several times, and the eyeball was strongly adducted by means of a pair of forceps grasping the conjunctiva over the insertion of the internal rectus muscle. A keratonyxis needle was then plunged through the sclera, just in front of the equator and below the external rectus muscle, and the membrane lacerated freely in several directions. The needle was then withdrawn, and an ophthalmoscopic examination at once made, the pupil being under the influence of atropia. This showed that the membrane had been completely divided in two places, and incompletely in one place. Atropia was instilled and the eye at once bandaged. The bandage was removed on the third day, and there being no sign of reaction vision was tested on the fifth day and found to have risen to $\frac{10}{200}$ without a glass, and with sph. — D 2 $\smile$ cyl. — D 1, axis 90°, to $\frac{20}{70}$. The patient was then permitted to go out, and on the eighth day left for her home. Three months later V = $\frac{20}{50}$ + with the above glasses, and an ophthalmoscopic examination showed that the divided ends of the membrane had retracted, leaving the optic disc and region of the macula exposed to view.

Case II.—Miss E. W——, aged twenty-six ; first seen October 19, 1885. Ten months before, the patient had been attacked by a serious inflammation in both eyes, only slightly painful in character, but attended by marked loss of vision. There was no external evidence of any ocular inflammation. The disease subsided in about two months, and the vision slightly improved in the right eye, but there has been no change in the latter for at least six months. The patient gives a distinct syphilitic history.

Present condition.—R. E., V = $\frac{1}{100}$; cornea and aqueous humor clear, iris normal in color and reaction, lens transparent ; a mass of filaments and membranes running like a mesh-work across the vitreous, the fundus appearing indistinctly through the meshes. L. E., V = $\frac{20}{30}$ — unimproved ; media clear except for some small floating opacities in the vitreous ; iris normal ; small patches of old choroidal inflammation, mainly in the equatorial region. This was considered an unfavorable case, but the operation was done on the right eye in the same position as in the first case, but with a broad needle with a double cutting edge. The ophthalmoscope showed that the membranous mesh-work had been incompletely divided in two places. Atropia and a bandage. The latter was removed on the third day ; no reaction ; V = $\frac{4}{100}$. The ophthalmoscope showed that the cut on the temporal side had gaped considerably. The vision was tested at the end of two weeks, and found to have risen to $\frac{15}{200}$, beyond which it did not improve. The patient was seen at the end of two months, and the same condition existed.

Case III.—Mrs. M. R——, aged thirty-five ; first seen October 26, 1885. Patient has been myopic since childhood, and four years ago had serious trouble with both eyes, particularly the left eye, accompanied by partial loss of vision and great intolerance of light, brought on probably by long-continued abuse of her eyes in doing fine embroidery. Since the attack subsided she has been more careful in the use of her eyes, and there has been considerable improvement in the vision of the right eye, but the left eye has remained very defective in vision. No history of syphilis or rheumatism. There is no external evidence of disease in either eye, except a tendency to divergence of the left eye.

Present condition.—R. E., V = $\frac{10}{100}$; with sph. — D 6 = $\frac{20}{50}$; some floating opacities in the vitreous ; general choroidal atrophy, most marked on temporal side of disc and downward in infero-temporal quadrant. L. E., V = $\frac{6}{70}$; with sph. — D 6 = $\frac{20}{200}$; numerous floating opacities in the vitreous, and one band of thin membrane running from near nasal margin of disc forward and outward to the ciliary region ; patches of choroidal atrophy all over fundus. Here the two-edged cutting needle was introduced on the nasal side of left eyeball in a corresponding position, and the single membranous band was thoroughly divided, as the ophthalmoscopic examination showed. There was no reaction, and on the fifth day V = $\frac{20}{70}$ with sph. — D 6. Two weeks later the vision was the same, and it remained unchanged for four months, since which time the patient has not been seen.

Case IV.—Miss E. F——, aged twenty-two ; first seen November 30, 1885. Patient has always been myopic, and has worn glasses for several years. Nine years before she had received a violent blow on the left eye, with immediate loss of vision, which was followed by severe inflammation, swelling of the lids, and great pain in the eye and head. As the inflammatory symptoms subsided the vision began to be restored, but there has been no change for a number of years.

Present condition.—R. E., V = $\frac{20}{200}$; with sph. — D 2.50 = $\frac{20}{30}$ +. The fundus presents the usual appearance of a myopic eye. L. E., V = $\frac{5}{100}$, unimproved ; pupil dilated and immovable ; lens slightly opaque at the periphery ; floating opacities in the vitreous of varying size and shape, and a large, thick, vascularized membrane, attached anteriorly to the outer ciliary region, and posteriorly to the retina on the nasal side of the disc, and entirely concealing the latter and the region of the macula from observation. Here the membrane was so dense that the slender cataract knife was employed, being introduced on the temporal side of the left eye through the sclera, and the membrane divided in the vertical direction. It was felt to give under the knife, and the ophthalmoscope showed a small hemorrhage, probably from the divided vessels of the membrane, lying on the membrane and floating in the vitreous. Some reaction followed this operation, but on the tenth day the eye was quiet, and V = $\frac{10}{100}$. The ophthalmoscope showed a retraction of the nasal end of the membrane. while both ends moved freely as the eye moved. There was no further improvement in the vision, though the case was watched for nearly a year.

Case V.—Mrs. M. N——, aged sixty-three ; first seen November 30, 1885. Patient has been excessively myopic from childhood, but has never worn glasses. Has had repeated attacks of some form of deep inflammation in the eyes. accompanied by deterioration of vision, from which she recovered each time with a steady loss of vision.

Present condition.—R. E., V = $\frac{3}{200}$, unimproved ; iris sluggish ; periphery of lens cloudy ; several broad, fine membranes stretching across the vitreous, apparently from side to side, floating with the movements of the eye, but fixed at either end, and permitting a very indistinct view of the fundus through their cobweb-like substance, where are signs of most extensive choroidal atrophy. Myopia of about D 16 with the ophthalmoscope. L. E., V = $\frac{3}{200}$; vitreous and fundus in about the same condition as the right eye. As both eyes were about alike, the operation was done on the temporal side of the right eye with the discission-needle, and the membrane extensively lacerated, as the ophthalmoscope showed. No reaction. On the fifth day V = $\frac{3}{200}$, but with sph. — D 14 it rose to $\frac{10}{200}$, and continued slowly to improve, until at the end of the second month it was $\frac{20}{200}$, the membrane having retracted on both sides, leaving a free vent.

Case VI.—Mr. J. C. R——, aged forty-two; first seen January 25, 1886. Four years ago he had a violent fall, striking on the right side of the forehead and supraorbital region. There was extensive laceration of the soft parts, and the bone was fractured. The vision of the right eye was affected at once, and grew steadily worse, so that in the course of a few weeks it was reduced to perception of light. Since then it has somewhat improved.

Present condition.—R. E., V = $\frac{2}{200}$, cornea clear, iris fluttering, and pupil immovable; lens in place and transparent; vitreous is crossed by a dense, broad membrane, running from outer margin of disc downward, forward, and outward; projection good in every direction; pupil easily dilated by atropia. L. E., V = $\frac{20}{20}$, media clear, and fundus normal. Here the slender cataract knife was plunged through the sclera on the nasal side, below the internal rectus muscle, and a long cut made through the membrane, but the ophthalmoscope showed no gaping of the edges—absolutely no reaction. On the sixth day there was a decided gape in the membrane, and V = $\frac{20}{200}$, the hole being oval in shape. There was no further improvement. The patient was seen in May, 1888, and the condition of the eye remained the same.

Case VII.—Mr. William B——, aged forty-five; first seen May 3, 1886. Syphilitic patient; has had repeated attacks of iritis in both eyes, and for more than a year the vision in the right eye has been steadily failing, and for several months it has been useless.

Present condition.—R. E., V = perception of light; field wanting in supero-nasal quadrant; cornea clear; iris discolored, and adherent to capsule of lens; pupil irregular and immovable, and only partially dilated by repeated instillations of atropia; lens apparently transparent; filamentous membrane stretching across vitreous nearly in horizontal plane. Tension − 1. L. E., V = $\frac{20}{30}$+; cornea clear; iris discolored and adherent to lens; lens and vitreous apparently clear. A detachment of the retina was supposed to exist in the infero-temporal region, probably directly connected with the membrane. This gentleman was told of the bad outlook, and that the chances of improvement were slight, while serious inflammation might follow the operation. He decided to risk it, and the small discission needle was plunged through the outer aspect of the sclera of the right eye, and a single sweep from above downward given to it, and it was then withdrawn. Somewhat violent reaction followed, which yielded to atropia, hot water, and a bandage, but no ophthalmoscope examination was made for three weeks. No change was discoverable in the membrane, owing to the adherent condition of the pupil, but the patient could distinguish the movements of the hand, and claimed that he noticed considerable improvement in the vision. He urged another attempt, but the danger of reaction was considered too great. The defect in the field remained the same.

Case VIII.—Mrs. E. H——, aged sixty-four; first seen May 10, 1886. Patient had never had any trouble with her eyes until about eighteen months ago, since which time the vision in both eyes has gradually failed, and she now complains of seeing everything through a mesh-work or veil.

Present condition.—R. E., V = $\frac{20}{30}$, unimproved. Ht. = D 1; cornea and lens normal, except at the periphery of latter, where there are numerous opacities; delicate cobweb membrane extending across the vitreous from the nasal side downward and outward. L. E., V = $\frac{20}{30}$, unimproved. Ht. about + D 1.75; cornea and iris normal; peripheral opacities in the lens; delicate cobweb membrane in the vitreous, not quite so extensive as in right eye. In this case an attempt was made to lacerate the membrane with the discission needle in each eye separately, but although it was readily torn, there was no gaping of the rents in the right eye. In the left eye, however, one of the lacerations gaped wide, but there was no improvement in the vision. The needle was introduced through the sclera on the temporal side in each eye. There was absolutely no reaction in either eye following the operation.

Case IX.—D. C——, aged fifty; first seen November 28, 1887. Twenty-five years ago this patient contracted syphilis, and had, among other constitutional symptoms, an inflammation in both eyes, beginning in the left eye, which ended in total blindness. The right eye was much less seriously affected. Both eyes remained quiet until six years ago, when the left eye became inflamed again. This attack subsided, and there was no further trouble till September, 1887, when the left eye became again inflamed and still remains so.

Present condition.—R. E., V = $\frac{20}{50}$ −; cornea clear; iris discolored, but freely movable; lens clear; large membraniform opacity in the vitreous, attached by a broad base to the nasal margin of the optic disc. L. E., V = 0, tension + 2; iridocyclitis; cloudy cornea; lens opaque, and lying in the anterior chamber; iris dilated ad maximum and adherent to the lens. The left eye was enucleated as a necessary preliminary to the operation on the right eye. Two weeks later, the needle with double cutting edge was introduced through the temporal side of the sclera, and an attempt was made to cut across the entire membrane, which, however, was only partially successful, as the membrane seemed to bend before the instrument. Some reaction followed, and it was feared that the vision might suffer, but on the sixth day the eye had become entirely quiet, and a laceration was discovered in the membrane, which had already gaped a little. On the twelfth day V = $\frac{20}{46}$ +, and even improved a little beyond this in the course of the next few weeks.

Case X.—Miss A. L——, aged thirty-two; first seen December 5, 1887. Two years ago the patient suddenly noticed a large black spot before the left eye, which rapidly obscured her vision. This has remained ever since, with alternate conditions of improved and deteriorated vision. Her sight is always worse at the menstrual epoch.

Present condition.—R. E., V = $\frac{20}{20}$; media clear and fundus normal. L. E., V = $\frac{20}{50}$ −; cornea, iris, and lens normal. At the posterior pole are spots of choroidal exudation, and stretching across the vision in every direction are numerous fine filamentous opacities, fixed at the ends and waving with the motions of the eye. The keratonyxis needle was plunged through the sclera at the point before indicated on the outer aspect of the eye, and the fine filamentous opacities swept in every direction by the needle. An ophthalmoscopic examination immediately afterward showed that apparently nothing had been accomplished, the filaments bending before the needle instead of being torn. There was no reaction and no improvement in vision.

Case XI.—Mr. George G——, aged thirty-five; first seen December 5, 1887. The patient has had defective vision in the left eye for several years, which came suddenly without any known cause, but which was probably a hemorrhage in the vitreous. He thinks the vision of the right eye has failed of late. Had a chancre nine years ago.

Present condition.—R. E., V = $\frac{20}{30}$ + unimproved; cornea, iris, and lens clear; refraction hypermetropic; faint, dust-like opacities in the vitreous; fundus apparently normal. L. E., V = $\frac{10}{200}$, unimproved; cornea, iris, and lens normal; broad but very delicate membrane in the vitreous, fixed but wavy, obscuring slightly the entire fundus; remains of an old chorio-retinitis. The double-edged broad needle was introduced in the position of choice on the outer aspect of the eyeball, and a single sweep of the needle made, from above downward. There was no reaction from the operation, and on the eighth day the ophthalmoscope showed that the membrane had been entirely divided, and the ends had retracted on either side almost out of sight. V = $\frac{20}{40}$. This has remained unchanged, the patient having been seen within the mouth, and the vitreous was found almost clear.

Case XII.—Mr. A. E——, aged forty-four; first seen

January 16, 1888. Patient has had defective vision in left eye for five years, dating from a sudden attack of almost complete loss of sight. Three weeks ago he again had a sudden obscuration of vision in the left eye, which during the past week has begun to improve.

Present condition.—R. E., V = $\frac{20}{20}$; media and fundus perfectly normal. L. E., V = $\frac{1}{200}$; cornea, iris, and lens normal. A membrane, pierced by numerous holes, stretches across the posterior part of the vitreous, adherent posteriorly to the margin of the optic disc; and floating in the vitreous, and at times obscuring nearly the entire fundus, are several blood-clots. The patient has grave cardiac disease, both hypertrophic and valvular. It was thought best to wait until the recent hemorrhage had at least been partially absorbed. On February 14th, the slender knife was introduced in the position of choice and several attempts made to lacerate the membrane in various directions. A somewhat violent reaction followed, and it was not until the fourteenth day that an ophthalmoscopic examination was made. There were still some blood-clots floating in the vitreous, but quite a large laceration was seen in the membrane and the vision was found to have risen to $\frac{20}{100}$. This slowly improved as absorption went on, and at the end of three months the vitreous was very much clearer and V = $\frac{20}{70}$ +.

Case XIII.—Mr. William S——, aged thirty; first seen January 30, 1888. This patient had a chancre in July, 1886, and after numerous constitutional lesions the left eye became affected in April, 1887, the attack having evidently been a choroiditis. The vision was markedly affected, but since the subsidence of the attack it has slowly improved.

Present condition.—R. E., V = $\frac{20}{20}$; media and fundus normal. L. E., V = $\frac{20}{100}$; cornea, iris, and lens normal. Some minute floating opacities in the vitreous, and a single strand of rather dense tissue extends directly from the temporal margin of the optic disc, forward and outward toward the periphery. As the narrow membrane seemed to be rather thick and dense, it was deemed wise to employ the slender cataract knife. This was introduced at the usual point in the outer side of the eyeball, and passed slightly upward, and then brought downward and withdrawn with a single cut. The ophthalmoscope was immediately used, and the membrane was seen to have been completely divided. No reaction followed, but the vision was not tested till the eighth day, when it was found to have risen to $\frac{20}{40}$ —. An examination of the fundus showed that marked retraction had taken place in the membrane, especially in the peripheral fragment, which had almost disappeared from view. Subsequently the vision improved slightly to $\frac{20}{40}$ +.

Case XIV.—Mrs. M. H——, aged twenty-four; first seen February 21, 1888. This patient has both cardiac and pulmonary disease. Was confined with her first child fourteen months ago, and almost immediately afterward had a sudden attack of loss of vision in the left eye. From this she slowly recovered, but this eye never quite regained its normal vision. Early in January, 1888, she had a similar attack in the right eye, while nursing her child, from which, in a week or two, she began to recover. On February 14th she again had an attack in the right eye. This patient has no sign of any renal disease.

Present condition.—R. E., V = fingers at four feet; cornea, iris, and lens normal; dense membranous opacities with wide meshes stretching all across the fundus and obscuring every detail, and numerous large blood-clots fixed on the membrane, or floating in the vitreous. L. E., V = $\frac{20}{70}$; cornea, iris, and lens normal. Broad, cobweb-like membrane in the vitreous, fixed posteriorly some distance below the margin of the disc, and attached anteriorly by a much broader base to the equatorial region upward and outward. I regarded the right eye as being in an almost hopeless condition, but decided to operate on it before attempting anything on the left eye. Owing to the density of the membrane the slender knife was used, introduced in the usual position through the sclera on the temporal side, and attempts were made to thoroughly divide the membrane in several places. The attempts were partially successful, but violent reaction followed the operation, accompanied by fresh hemorrhage into the vitreous, which reduced the vision to perception of light. This subsequently improved to about what it was before the operation, and the ophthalmoscope showed several holes in the membrane. One month later the left eye was operated upon at a corresponding point in the sclera, the keratonyxis needle being used, and the cobweb membrane was thoroughly lacerated. Vision improved almost immediately to $\frac{20}{40}$ +, the central retraction of the membrane being considerable. This patient is still under observation.

Case XV.—Mrs. W. L——, aged fifty; first seen March 14, 1888. This patient has had gradually failing vision in both eyes, without any decided or sudden inflammatory attacks, for more than two years. There is irregularity of the heart's action, but no very decided organic lesion.

Present condition.—R. E., V = $\frac{20}{200}$; well-marked arcus senilis; faint opacities at periphery of lens; delicate band of connective tissue extending across the vitreous from above and outward, downward, and inward; signs of old choroiditis. L. E., V = fingers at two feet. Same conditions in cornea and lens as in the other eye. Broad, rather thick, irregularly shaped membrane in the vitreous, extending from near the nasal margin of the optic disc upward and outward to the equator. In this patient the operation was done on both eyes at the same time, as her stay in the city was limited. On the right eye the keratonyxis needle was used, while on the left eye the double-edged cutting needle was employed, the puncture being at a corresponding point on the outer aspect of each eye. There was some reaction following the operation on the left eye, which, however, subsided within the first week. An ophthalmoscopic examination showed complete division of the delicate membrane in the right eye, with marked retraction of the divided ends, and a large hole through the thicker membrane in the left eye. One month after the operation an examination showed in the R. E., V = $\frac{20}{50}$, and in the L. E., V = $\frac{20}{200}$.

Of the seventeen operations done on fifteen patients, fourteen gave decided improvement in the vision, and three proved failures. In no case was there any loss of vision from the operation. It seems proper to conclude that the operation is a suitable one in certain cases, and is justified by the results obtained. It would seem wise to wait in any case until all inflammatory symptoms have long subsided before attempting to divide the resulting obstructing membranes, no matter whether caused by hemorrhages into the vitreous, or by a hyalitis, the result of choroiditis. The eye should be absolutely free from all irritation before attempting any such surgical interference.

51 West Thirty-sixth Street.

Traumatic Separation of the Superior Tibial Epiphysis.—Dr. F. T. Hueston reports the following case in the *British Medical Journal* of July 21, 1888. R. L——, eight years of age, was admitted into the Adelaide Hospital on May 7, 1888, suffering from the result of an accident which occurred in the following manner: On May 1st he was running in a school-room from two other boys, and, in order to escape, attempted to force his way between two desks, which were then pushed together by the other boys, the injury occurring while attempting to wrench his leg free. At the time of the accident he had but little pain, and was able to walk home, where he was kept in bed and stupes applied, a large amount of swelling supervening in a few hours. On examination all the local evidences of acute synovitis of the knee-joint were found, while free movement was to be obtained between the superior epiphysis of the tibia and the shaft, there being, however, no crepitus. The author was able to find only four cases of this nature on record.

COMPRESSED AIR BELOW THE SEA-LEVEL.

By WALTER LINDLEY, M.D.,

LOS ANGELES, CAL.,

VICE-PRESIDENT OF THE STATE MEDICAL SOCIETY OF CALIFORNIA; PROFESSOR OF OBSTETRICS IN THE MEDICAL COLLEGE OF THE UNIVERSITY OF SOUTHERN CALIFORNIA, ETC.

I RECENTLY read[1] that an American of wealth was establishing a sanatorium in the valley of the river Jordan, near the Dead Sea. He ascertained that a bronchial affection was relieved where the barometric pressure was great, as it is in this valley of the Holy Land. This is the most marked depression on the face of the earth, being twelve hundred feet below sea-level. This gentleman makes the reasonable assertion that where atmospheric pressure is greatest, as in the depressions, respiration is easist.

In the eastern part of San Diego County, about one hundred miles from Los Angeles, is a depression traversed by the Southern Pacific Railroad, known to geographers as the San Felipe Sink, but commonly called—on account of the innumerable shells spread over its surface—the Conchilla Valley.

The unobserving transcontinental traveller over the Southern Pacific Railroad would travel the one hundred miles west of Yuma—on the Colorado River—without giving a glance out of the car-window, but would think he was in the Colorado desert, and wish the train would go faster; yet this very spot is one of the most remarkable on the face of the globe.

Dr. J. B. Widney,[2] of Los Angeles, while surgeon in the United States Army, crossed this region with troops twenty-one years ago. He then noticed surrounding this territory a well-defined line along the mountain-sides, always at the same level. Above that line the rocks are sharp and jagged, showing that for ages the water had stood at that level. He says, "I found it to be the old beach of a sea." I find nothing else noted of this country until the surveying party of the Southern Pacific Railroad, in running the line from Los Angeles to Yuma, found that sea-level was at the point where Dr. Widney had noted the ancient beach. They then gradually descended to the south until they reached a depression of two hundred and sixty-eight feet below sea-level, at a point near Salton.

This basin is about one hundred and thirty miles in length by thirty miles in average width. The deepest point is about three hundred and sixty feet below sea-level. Along the northern margin of this basin, right up against the mountains, are great numbers of date-palms. These tropical trees are indigenous to this valley, and many of them reach a height of eighty feet. When ripe, a single bunch of the fruit weighs one hundred pounds. It has a taste very similar to the date-palm of commerce. The tree has large fan-leaves, and is the same as can be seen in almost every park and yard in the towns of Southern California. The passenger on the Southern Pacific Railroad, by glancing out of the north side of the car at Indio, can see these giant sentinels keeping silent vigil over the plains beneath them.

At Salton, on the Southern Pacific Railroad, the surface of the earth for nearly ten miles square is covered with a crust of salt from four inches to a foot thick. I stopped there in midsummer and went out on this great white field about noon. The mercury indicated 105° F. in the house, but out in the sunshine, with the dazzling reflection from the glistening surface that extended for miles on each side, the temperature was probably 130° F. The workmen out in this peculiar harvest-field were as cheerful as any set of men I ever saw, and there was far less exhibition of suffering from heat than is to be seen, ordinarily, in July, in the wheat-fields of the Mississippi Valley. The low relative humidity explains the total absence of sunstroke here. The atmosphere in this region, adulterated by the chlorine gases emanating from the salt-beds, must be nearly aseptic. There are extensive mills here for grinding the salt. It is not put through any system of purification, but, after grinding, proves to be excellent for table use. Several hundred tons are thus prepared every month and shipped away.

A few miles east of here are the famous mud volcanoes, which are equal in wonder to the geysers of this State. Owing to the treacherous character of the ground around them they have never been thoroughly examined. Professor Hanks, the State mineralogist, undertook it, but breaking through the crust he was so severely burned that he was compelled to abandon his investigations.[1] Here is an extensive, almost unexplored field for some adventurous scientist.

Indio is the place to stop and make headquarters for tours through this interesting country. It is the principal station in the valley, and is near the northern rim of the basin, being only twenty feet below sea-level. The sandy plains around Indio were formerly considered a hopeless barren waste, but the advent of the railroad has made great changes. Good water is supplied by surface wells; but in order to have water for irrigation, artesian wells have been bored. There is one two and three-fourths miles east of Indio that is now flowing one thousand gallons per hour. This flowing water was reached at a depth of only one hundred and fifteen feet, after boring through layers of sand, clay, sand, tough blue clay, clay, coarse gravel, clay, and sand. Oranges and various other kinds of fruit are being grown here, and melons, tomatoes, and berries ripen several weeks earlier than at Los Angeles and other places near the coast. There are in this vicinity about forty thousand acres of excellent land. The visitor here, on witnessing the water flowing from the artesian wells, the grass growing, the melons ripening, and the peach-trees blooming, can fitly say with Isaiah: "The Lord shall comfort all the waste places. He will make the desert like the garden, and the desert shall rejoice, and bloom as the rose. For in the wilderness shall waters break out, and streams in the desert. And the parched ground shall become a pool, and the thirsty land springs of water."

In this valley live about four hundred of the Cohuilla Indians. This is an interesting tribe. Dr. Stephen Bowers, in a paper read before the Ventura County Society of Natural History, March 5, 1888, said that he believed them to be of Aztec origin. They are sun and fire worshippers and believe in the transmigration of souls, and that their departed friends sometimes enter into coyotes, and thus linger about their former habitation. They practise cremation. Their principal article of food is the mesquit bean, which they triturate in mortars of wood or stone, after which the meal is sifted and the coarser portion is used as food for their horses and cattle, and the finer is made into cakes for family use.

The Agave, or Century-plant, which is indigenous here, is also much used for food. The roots, roasted, taste like stewed turnips, while the stem, roasted, is said to taste like baked sweet-potatoes. From this plant they also make the Mexican beverage *pulque*, which has about the same alcoholic strength as beer. The ethnologist can, by gaining their confidence, get much interesting information from these very peaceable Indians.

I found at Salton and Indio asthmatics, rheumatics, and consumptives, all of whom reported wonderful recoveries. Some of these stories I accepted *cum grano salis*, which quotation is, by the way, especially applicable to the salt-fields. These asthmatics and consumptives claim that the farther they get below sea-level and the dryer the atmosphere, the easier they breathe. The rheumatics claim that the heat and dryness improves the circulation, and thus relieves them.

My stay was not long enough to make any trustworthy observations, but it occurred to me that, aside from dryness—mean annual relative humidity certainly not over twenty-five—and equability, there was considerable atmospheric pressure at a point three hundred and fifty feet below sea-level, and that we had here moderately compressed air on a large scale. In a recent paper[1] on the use of the pneumatic cabinet, the author, from many cases in practice, shows that compressed air relieves asthmatics and cases of phthisis. He says the compressed air will gradually force its way into every part of the lung, in order that the pressure may be the same on the inside as on the out. While the proportion of oxygen is, of course, not increased, yet there is an increased quantity in a given space, and we really have the oxygen treatment here on an extensive scale.

[2] See California of the South, second edition. New York; D. Appleton & Co. 1888.

[1] Dr. Stephen Bowers, in the Golden State, March 3, 1888.

The physician may say that at from two hundred to three hundred and sixty feet below sea-level the pressure would not be as much as in the cabinet. That is true, but the patient goes into the cabinet for, say half an hour, three or four times a week, while if he is at a point like Salton, he is breathing this moderately compressed air all the time, day and night. This is simply on the principle of the pneumatic chamber of Tabarie, the first one ever employed. This is the method recommended by Dr. A. H. Smith.[2] He refers to the therapeutic value of the increased amount of oxygen inhaled. He says compressed air is useful in catarrh of the mucous membrane, in acute and subacute inflammation of the respiratory mucous membrane, in restoring the permeability of air-tubes occluded by exudation or otherwise, in asthma, in pulmonary hemorrhage, in pleuritic effusion, in simple anæmia, in inveterate cases of psoriasis and ichthyosis, and in the various forms and stages of phthisis. He does not recommend it in pulmonary emphysema. Dr. Smith says compressed air should be used promptly and perseveringly on the earliest recognizable signs of apical catarrh in those predisposed to chest disease. He also especially recommends it as an alterative.

Of course my deductions are all tentative, but I hope by calling attention to this unique region to gain the assistance of intelligent observers.

If a phthisical or asthmatic patient of considerable vigor intends coming to Southern California, his physician might be justified in suggesting that—except during the summer months—he stop at Indio, and from there test the climate of this basin. If not suited or benefited, it is but two hours' ride by rail to Beaumont, a delightful resort, with excellent accommodations, two thousand five hundred feet above sea-level; but two hours more to the pine forests in the San Jacinto mountains, from six thousand to ten thousand feet above sea-level, or to Riverside, Monrovia, Pomona, or Whittier, all about one thousand feet above the sea; or to Los Angeles, three hundred and fifty feet above sea-level; or to Santa Monica, Long Beach, Santa Barbara, or San Diego, directly on the coast, and but nine hours' ride by rail and boat to Catalina Island, twenty-five miles out at sea, where a typical ocean atmosphere can be enjoyed. Thus an error in location can be quickly corrected.

NOTE. — OTHER PLACES BELOW SEA-LEVEL. — *Sink of the Amorgosa* (Arroyo del Muerto), in Eastern California, two hundred and twenty-five feet below sea-level. *The Caspian Sea*, eighty-five feet below sea-level. *Lake Assal*, east of Abyssinia in the Afar country, eight miles long and four miles wide, is about seven hundred and sixty feet below sea-level. Its shores are covered with a crust of salt about a foot thick. This salt is a source of revenue to the Afars, as they carry it by caravans to Abyssinia, where they find a ready market. There are several other depressions about six hundred feet below sea-level in this vicinity. The noted oasis Siwah, in the Libyan desert, three hundred miles west of Cairo, is one hundred and twenty feet below sea-level. Here are beautiful date-palm groves, and here also the apricot, the olive, the pomegranate, and the vine are extensively cultivated. In this same desert is the oasis *Araj*, two hundred and sixty-six feet below sea-level. There are also numerous other depressions in the desert portion of Algeria and at various points on the Sahara Desert.

NOTES ON THE GERMICIDAL ACTION OF PEROXIDE OF HYDROGEN.[1]

By H. GIFFORD, M.D.,
OMAHA, NEB.,
OPHTHALMIC AND AURAL SURGEON TO THE B. & M. R R.

In spite of the extensive use of peroxide of hydrogen and the commonly received opinion as to its value as a germicide, its germ-killing power has not, so far as I can learn, been investigated thoroughly. The prevalent impression of its value probably rests largely on the experiments of Kingzett, Guttmann, and Miguel; but these, which were not conducted with the improved methods of bacteriology, prove nothing as to its germicidal power, but simply that in certain small proportions it prevents the development of some microbes (species not determined). Wecks,[2] using modern methods, found, devoting a short paragraph to the subject, that the "hydrogen dioxide, formula HO_2," [*sic*] destroyed pyogenic germs in exposures of one to one and one-half minute. He gives no idea, however, of the strength of the solution used, and the impression given by him of the extreme instability of the compound requires some correction. I have therefore thought it worth while to test the substance in various strengths on the bacilli and spores of anthrax, and on the white and yellow pus cocci.

The article used was Charles Marchand's fifteen-volume solution. The methods were, 1, that of Koch, in which threads, impregnated with the germs, are subjected to the influence of the germicide, and then, after washing in sterilized water, placed on the surface of the nutrient medium; 2, the following plan, which is somewhat simpler and more expeditious: A small platinum loopful of the germs is rubbed up rapidly in the germicidal liquid; from this emulsion a loopful, containing many hundred germs, is, after the desired length of exposure, transferred to a test-tube containing melted agar or gelatine, in which it is thoroughly shaken up. The tube is then placed in the incubator in a nearly horizontal position, and if any germs are left alive they develop, scattered through the mass. This method has the advantage, without the bother, of plate-cultures, or even of Esmarch's roll-cultures, of giving an approximate idea of the proportion of germs that survive a given exposure. The method is open to the theoretical objection that the minute amount of the germicide introduced into the culture medium might prevent the growth of germs not really killed, but the weight of this objection is easily removed by a few control-experiments. Since completing my work I notice that Martens[3] has used a similar plan, and doubtless it has been used by many others, though I have not seen it mentioned.

It was found that the fresh fifteen-volume solution killed the white and yellow cocci and the anthrax bacilli in exposures of three-quarters to one and one-half minute, and fully developed anthrax spores in three to four minutes. When the second method was employed, with Koch's threads, the results were more inconstant, and the average time required for killing was somewhat longer (*i.e.*, three to five minutes for anthrax spores, and one to two and one-half minutes for the cocci and bacilli). This was probably because, in the dried clumps on the threads, some of the germs were shielded from the action of the peroxide. Also, when mixed with blood and pus (*i.e.*, under approximately natural conditions), the pus germs were killed in one to two minutes.

To eliminate the possibility that these results were due to the free acid which the stable solutions of the peroxide contain, a gravimetric analysis of a sample was kindly made for me by Mr. Bruce of the Union Pacific Laboratory. showing the presence of 0.118 per cent. of free HCl. This result differs considerably from the statement, in the announcement of Marchand's solution, that the latter contains but "$\frac{1}{3000}$ phosphoric acid and $\frac{1}{6000}$ sulphuric acid," still the proportion is too insignificant to account for the results achieved. A full-strength neutral or alkaline solution is difficult to obtain, as the H_2O_2 decomposes very rapidly on the addition of the alkali (sodium bicarbonate) even when it is kept at a low temperature by the aid of ice, during the neutralization; but a slightly alkaline mixture formed by the addition of a drop of a saturated solution of sodium carbonate to twenty drops of the peroxide solution, is still actively germicidal.

[3] Virchow's Archiv, cxii., 2.

The statement of Wecks, therefore, applies correctly to the fresh fifteen-volume solution, but his report of the instability of the solution used by him would lead one to infer that exposing it to ordinary room-temperature for a few hours, to say nothing of days, would certainly destroy all valuable germicidal power. I found, however, that a solution exposed for forty days to a temperature of 68° to 75° F., in an ordinarily corked flask, still killed the yellow pus cocci in ten to eleven minutes.

While, however, the enthusiasm with which the peroxide has generally been received as a germicide can be considered justified if the fresh fifteen-volume solution is referred to, the same cannot be said of some of the dilutions recommended. The instructions accompanying the Marchand solution advise diluting with about four times its bulk of water, for use on "mucous membranes as injections, etc." A dilution of this strength was found not to have killed the pus cocci after an exposure of thirty minutes, a result which practically bars it as a germicide, though for its cleansing action it may still be valuable, especially when combined with another antiseptic, as has been recommended by Dr. Macrae, of Council Bluffs.[1] The fresh solution, diluted with an equal volume of water, killed the pus germs after a three to four minutes' exposure; diluted with twice its bulk of water, it destroyed all but a minute fraction of the germs, after an exposure of ten minutes.

The fifteen-volume solution is sharply irritating to the conjunctiva and nasal mucous membrane, and even the weakest solution mentioned in the announcement (two to three volumes) instead of being "bland as water" causes considerable smarting of the eyes and nose for a few minutes.

Regarding the mode in which the peroxide acts, the common impression, fostered by alleged observations, that the bacteria and pus globules are rent asunder, and reduced to a mass of débris by the violence of the decomposition, is erroneous. After an exposure of an hour, all active ebullition having ceased, I have failed to observe any appreciable change in the appearance of anthrax spores and bacilli, though they were killed dead as stones; and pus globules, after many hours' exposure, though changed in appearance, still retain their contour. Neither is it, in my opinion, the nascent oxygen which kills the germs. Formerly, in common with many others, I believed that it did, and would watch with glee the mass of bubbles resulting from an instillation of the peroxide into a suppurating ear, considering each bubble the signal of the death of many micrococci. As a matter of fact, however, a partly decomposed alkaline solution, which foams much more furiously (*i.e.*, gives out nascent oxygen more rapidly) than a fresh slightly acid solution. is much less efficient than the latter. The germs, apparently, are not killed by the ozone liberated, but are simply poisoned by the undecomposed peroxide just as they are by carbolic acid and sublimate. In other words, while the ebullition, by its mechanical effects, is what makes the peroxide valuable as a cleanser, when it comes to germ-killing, with a solution of a given strength, the less bubbling the better, except in so far as it favors the access of undecomposed peroxide to germs protected by secretions.

[Since reading the above paper, I have first noticed the work of Van Hettinga Tromp (Ref. in "Centralblatt für Bacteriologie," III., 25) who finds that H_2O_2 in the proportion of $\frac{5}{10.000}$ kills anthrax spores in twenty-four hours, typhus bacilli in five minutes, and that cholera bacilli are killed in less than five minutes by $\frac{1}{10.000}$. Unless typhus and cholera bacilli are especially susceptible, these results would indicate a greater germicidal power than I have found, as a fifteen-volume solution is supposed to contain something more than three per cent. of the peroxide; but without knowing just what preparation Van Tromp used, a profitable comparison of our results can hardly be made.]

THE STERILIZATION OF MILK.

By FREDERIC M. WARNER, M.D.,

VISITING PHYSICIAN TO OUTDOOR DEPARTMENT OF BELLEVUE HOSPITAL (DISEASES OF CHILDREN).

A PROBLEM which occurs to every general practitioner to solve, with greater or less frequency, is the successful rearing of children which have been, from some cause or other, deprived of the maternal nourishment; to this end various foods have been devised—some good, others bad, and all expensive.

After experimentation with, and trial of, most of these, I have come back to cows' milk, properly prepared, as the best substitute at our command.

This summer the bottle-fed children under my care have, with the exception of an occasional slight diarrhœa, done uniformly well, and this has tested, to my complete satisfaction, the method employed to render their food digestible and aseptic.

Since the publication of Dr. Jeffries'[1] interesting article I have caused the milk consumed by all my artificially reared children to be prepared in the following manner: Into an ordinary cooking steamer, which can be bought at any hardware store, a couple of inches of water is put and brought to the boiling-point; the milk, which is the infant's allowance for the next twenty-four hours, is placed in as many nursing-bottles as are used during that period of time. These bottles, having been previously placed in an oven for a quarter of an hour, are now stoppered with cotton-wool, and put on the perforated plate in the steamer, not touching each other, the cover shut tightly down and the whole allowed to steam for half an hour.

As will be readily seen, by this method all germs are destroyed, and if the milk is left stoppered and in a cool place, it will keep a long time. In the course of some experiments which I have been making, I find that, to-day, milk which was steamed exactly five weeks ago, is perfectly sweet and good.

When feeding-time comes, the woollen cork is removed and lime-water and sugar-of-milk are added. A nipple taken out of boiling water is put on, the bottle warmed, and the child's food is ready for administration.

Until six weeks old the proportions of lime-water and milk are half and half, with a teaspoonful of sugar-of-milk. About three ounces of this mixture will be taken every two hours; from six weeks to three months, one-third lime-water, and from this time gradually diminish the amount. I prefer using the ordinary cooking-steamer to the somewhat elaborate and costly apparatus of Sophlut for the sterilization of milk, for the reason that it is inexpensive, easily kept clean, and does not bewilder the overtaxed mother or nurse with elaboration of detail.

In closing I wish to merely emphasize the fact that a bottle must be used but once; immediately after the child has nursed all it will, the remainder of its contents must be thrown away, the bottle washed, and placed in the sun and air.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, September 1, 1888.

THE FLY AS A CARRIER OF DISEASE.

It is a popular belief that malignant pustule and certain other affections may be propagated by the bites of flies, and it has also been asserted that inoculation of yellow fever may be effected by the stings of mosquitoes. It is readily conceivable that flies or other insects, lighting upon pus or other material containing pathogenic micro-organisms, may soil themselves with the matter, and thus carry it to the surface of a small wound, or to food which will later be eaten. As long ago as 1883 Grassi stated that he had found the ova of certain intestinal parasites, such as tænia solium and oxyuris, unaltered, in the intestines of flies. Two years later Marpmann reported the results of certain experiments which he had made with micrococcus prodigiosus and bacillus fœtidus. He fed flies with potato-cultures of these micro-organisms, and obtained the same micro-organisms in cultures made from the intestinal contents of the same flies.

Dr. Giuseppe Alessi was led, from a consideration of the importance of these results, to undertake a further series of experiments with some of the known pathogenic micro-organisms (*Archivio per le Scienze Mediche*, vol. xii., No. 3, 1888). It will suffice here to relate briefly his mode of procedure and the results obtained in his experiments with the tubercle bacillus. He took some sputum from tuberculous patients, which he had found to contain the specific micro-organism, and placed it upon glass plates under a screen. He then put some flies under the screen and left them there for several days. At the end of this time he removed the intestines from the flies and made some cover-glass preparations from them, staining them by the Koch-Ehrlich-Weigert method. These preparations, examined under the microscope, showed the presence of large numbers of the bacilli. The experiments were repeated a number of times, and always with the same results.

He then examined the dejections of the flies which had been fed on phthisical sputa. For this purpose he placed a sheet of paper on a wire framework under the fly-screen, and examined the fæces there deposited by the same method of cover-glass preparations and staining. He found that these fecal matters contained the bacilli in great quantities, the organisms being here much more numerous than in either the intestinal contents or the sputa. It was thus shown that flies ingest, along with the sputum, the specific bacilli, and that the latter are found unaltered in the intestinal canal and in the fæces of the insects. As a control experiment he examined the intestinal contents and the excrement of other flies caught in the laboratory, which had not been fed on the phthisical sputum, but in no case found the specific micro-organisms.

Having ascertained that the flies ingested and passed in their fæces the tubercle bacilli, the next step was to learn whether the micro-organisms were destroyed in this journey, or whether they were still alive and had retained their virulence. To determine this fact he inoculated healthy rabbits with the excrement of these flies, introducing it into the anterior chamber of the eye. He always used the dried fæces, having previously examined it to determine the presence of the microbes. The immediate result of this inoculation was always an inflammation, more or less violent in character, but this disappeared in the course of eight or ten days, and the wound healed completely. A few days later a white point appeared in the centre of the crystalline lens, and then a little nodule was seen at the border of the iris, or a white filament stretching over the pupil. In from twenty-five to thirty-five days the entire pupil was invaded with a dense white cloud, and the peripheral ring of vessels was seen to be strongly injected. The iris, seen by oblique illumination, was of a dirty yellow color. Finally the cornea became gradually clouded so that the further intra-ocular changes could not be observed. An examination under the microscope of matter taken from the corneal ulcers showed the presence of large numbers of the tubercle bacilli, thus supplementing the clinical evidences of the virulence of the micro-organism.

Dr. Alessi made a number of additional experiments with the microbes of cholera nostras, typhoid fever, and charbon, and with staphylococcus pyogenes aureus, feeding flies with pure cultures of these micro-organisms, and in each case he obtained the same results as related above in the case of the tubercle bacilli. In every instance he showed that the micro-organisms were not digested by the insects, but passed through the intestinal canal unchanged, preserving their vitality fully, and being capable of further culture after their journey.

It would be easy to draw most alarming conclusions from the results of these experiments as related by Dr. Alessi. It does not necessarily follow, of course, that, because it has been shown that a few pathogenic micro-organisms can be carried from place to place by flies, all can be so transported; but, nevertheless, it suggests a possibility of such an occurrence. If this were the case, simple isolation of a patient suffering from a contagious disease would not be sufficient to prevent the spread of the malady, for the flies might readily carry the micro-organisms from one room to another, from one floor to another, or from house to house in the same portion of the city. But practically, even admitting the author's conclusions, which must necessarily be confirmed before being generally accepted, there is little to cause alarm to the most timid. If flies were such active agents in the transmission of disease we ought to have our epidemics in summer; but, in point of fact, we find most of these diseases more prevalent in winter, at a season when the house-fly is at rest. It nevertheless furnishes one argument more pointing to the necessity of the immediate and thorough disinfection of all the excretions from the body of one suffering from contagious disease, a matter which everyone recognizes the need of, but which everyone, we fear, does not insist upon as he ought.

WOMEN PHYSICIANS IN MEDICAL SOCIETIES.

OUR friends of the Quaker City have at last realized that there is no good reason why a properly educated and legally qualified female practitioner may not be admitted to their County Society, and yet it has taken several years to bring about this result. Even in the present instance the vote was a close one. We both honor and congratulate the pioneer in her efforts to secure for her sex their due professional recognition.

Professional conservatism is hard to overcome. Having the great past at its back, it has in argument to act only a defensive part. The burden of proof devolves upon those who desire a change. After the latter have manfully fulfilled their part, the conservatives, forced to yield one point after another, fall back upon their own conservatism without argument, for a final stand. This is such a rapid age that this last defence is soon undermined, and the beleaguered party eventually capitulates.

In this instance it appears to have done it very gracefully. The advocates of the admission of women to the Philadelphia Society publicly acknowledge that they "owe her election to the forbearance, good-will, and great-heartedness of our friends, who have for so many years *successfully opposed* our efforts to gain recognition of women physicians in that body." The writer of these words would make a good diplomat. He is able to retain his own convictions and state his triumph over his opponents in terms complimentary to the latter.

The work of the women's medical colleges in our large cities has been most commendable during the past few years. Our local institution has long had a graded course, and the thoroughness of its instruction has been superior, if anything, to that given in the larger institutions for men. In the clinical department it has, we think, been decidedly superior. No wonder, then, that the graduates have at once stepped into the ranks of the progressive elements of the profession. Their own work has been the best justification for their admission to the Societies.

THE OVERCROWDING OF THE MEDICAL PROFESSION.

IT is generally admitted that the number of physicians in this country is much greater than is needed to attend to the wants of the people, and far too great to be compatible with the best interests of the medical profession. In his annual address at the Cincinnati meeting of the American Medical Association, the late Dr. Garnett referred to this overcrowding, and used it as one of the arguments in favor of a higher medical education. "That the professions of law and medicine are overcrowded in this country," he said, "no man of common observation will deny. The ratio of professional men in the United States to the population exceeds that of any other country in the civilized world, so that any legitimate means of checking this evil which can be devised and carried into practical effect must be hailed by the medical world, as well as the general public, as an inestimable boon." The speaker estimated that the ratio of practising physicians in the United States to the population was about as 1 to 580.

The general belief seems to be that this ratio is not decreasing, but that, notwithstanding the rapid increase in population, the proportion of the latter to each physician is constantly growing less. It is gratifying, therefore, to learn from the report of proceedings of the quarterly meeting of the Illinois State Board of Health, held in Chicago in June last, that this is not the case.

Dr. Rauch, the Secretary of the Board, referring to Dr. Garnett's address, shows that there is not so great cause for alarm, but that the tide has apparently begun to turn. Quoting from the forthcoming report on Medical Education, he says that, notwithstanding the growth of population, the total number of medical students has never yet reached the proportions attained in 1882–83. The sessions of that winter were attended by 13,088 students; of 1883–84 by 12,763 students; of 1884–85 by 11,975 students; of 1885–86 by 12,321 students, and of 1886–87 by 12,948 students. Although there was a gain last year of 627 students over the attendance in 1885–86, the aggregate in 1886–87 was still 140 less than in 1882–83.

Not only is the absolute number of students growing smaller, but what is of perhaps even more importance, as indicating a better quality of the finished product, is the fact that the percentage of graduates to the total number of students is steadily diminishing. In 1882–83, out of every 1,000 matriculates 322 were graduated, taking both the United States and Canada and all schools of practice into the account. In 1886–87 only 294 out of every 1,000 matriculates were graduated. In the United States alone, in 1882–83, out of every 1,000 matriculates 331 were graduated, while in 1886–87 only 305 out of every 1,000 matriculates were graduated. Thus it is seen that, while the population increases—according to the census authorities—at the rate of two per cent. per annum (exclusive of the increment by immigration), the number of new graduates entering the profession was nearly eight per cent. less in 1886–87 than it was in 1882–83.

The causes which are working to produce this good result are chiefly two. In the first place, it is getting to be more commonly understood by the laity that the physician's calling is not an easy nor a lucrative one, and that a young man whose ambition it is to acquire a fortune cannot choose a less certain means of attaining this end. But the second, and more active, cause is the gradual evolution of the medical school from a business college to an institution for scientific training. The effects of a demand for a preliminary education, of a graded course of studies, and of a higher standard of qualifications for graduation are beginning to be felt. The number of graduates is less, and the proportion of well-educated men among them is greater.

The example of the leading medical schools of the country, and the influence of an awakened professional opinion, will doubtless be able to raise still higher, rather than to lower, the educational standards now in force. But it must in justice be admitted that to the work of the Illinois State Board of Health, and of its able and untiring Secretary, Dr. Rauch, much of the credit is due for the improvement now being made in the methods of medical study throughout the country.

THE MECHANICAL TREATMENT OF ERYSIPELAS.

THE methods hitherto employed in the treatment of erysipelas may be divided into the medicinal and the operative. The former is, of course, the older, and it is to Kraske that the more modern method of scarification, the operative method, is attributed. He did not originally employ multiple scarifications in order to render more effectual the action of antiseptics locally applied, as was done later, but rather to relieve tension and to give exit to the septic fluids. Riedel modified Kraske's method by making incisions two or three inches in length on the borders of the erysipelatous area, instead of multiple scarifications in the diseased part itself. Both these methods have given good results, but they have some serious disadvantages. The incisions cannot be made on the face or other exposed parts, on account of the disfiguring scars which remain, and even when the disease is on the body it is no light matter to the patient to be cut so often and in so many places.

A new method, called by the author the "mechanical" method, is proposed by Dr. Anton Wölfler, in an article published in the *Zeitschrift für Therapie* of July 15, 1888. He was led to its adoption from a consideration of Barwell's plan of covering the erysipelatous area with white paint. He found, however, that simply painting the part was not sufficient, but that it was necessary to cover the diseased skin with some waterproof material retained by a bandage. Further experience showed him that, when the bandage became loose, the erysipelas was very apt to spread, and he then adopted the practice of sealing the covering with traumaticin, a solution of gutta-percha in chloroform. This answered the purpose of keeping the disease within bounds very well, as a rule; but in certain parts, where there were many inequalities of surface and where the skin was very movable, the erysipelas would occasionally escape from under the protective, necessitating an extension of the traumaticin dressing. The author then resorted to strapping with adhesive plaster, and had no further trouble. He reports over twenty cases successfully treated with the traumaticin or adhesive plaster. The disease process was confined to the area covered by the dressing, the temperature speedily fell, and the patients made a rapid recovery.

Dr. Wölfler regards the action of the compressive dressing as a purely mechanical one in preventing the invasion of new territory by the pathogenic cocci. It is probable, he says, that the microbe soon exhausts the material for its sustenance in the skin, and, unless it can spread to the neighboring healthy parts, it quickly dies. The operative methods prevent this spread by dividing the small vessels in the skin, thereby producing extensive capillary thrombosis, and the pressure of the traumaticin or adhesive plaster exerts a similar restraining influence.

ENLARGEMENT OF THE LIVER IN RICKETS.

THAT rachitis is a disease of general malnutrition, and not affecting the bony framework alone or primarily, is now well recognized. In many cases, indeed, which are now regarded as rachitic, the osseous evidences of the disease are but slightly marked, or even absent, and the muscles and ligaments, the brain, or the intestinal canal are the parts most affected. The liver and spleen are also often involved, as is shown clinically by their increase in size. The minute changes in these organs have been studied in some detail, but not sufficiently, as yet, to enable us to determine precisely what their nature is.

In the Birmingham *Medical Review* for August, 1888, Dr. Edgar Hogben reports the results of a series of histological observations which he has made in cases of enlargement of the liver in rachitic children. He took pains to exclude all those cases in which there was a suspicion of tuberculosis, syphilis, or alcoholism, an instance of which in a young child he refers to in the article. The liver was, as a rule, tough and solid to the touch, and much heavier than its size would lead one to expect. Its surface was smooth, and of a color varying from that of deep congestion to the red mottling of fatty infiltration. There was in all the cases an increase in the fibrous connective-tissue elements of the organ, and sometimes a fatty infiltration of the hepatic cells was found associated with it. The fibrous growth was marked in the interlobular connective tissue surrounding and isolating the individual lobules. In the immediate neighborhood of the interstitial growth, and at the periphery of the lobules, there was in places a small-celled infiltration, derived apparently from the interlobular connective tissue, and encroaching upon the hepatic cells at the margin of the lobules. Occasionally there was a very marked thickening of the coats of the bile-ducts, and there seemed also to be a multiplication of the biliary canaliculi.

Of course, it is necessary to exclude other possible causes of this cirrhotic process before it can be definitely referred to rickets. Dr. Hogben endeavored to do so, yet, when there are so many sources of error a larger number of cases is necessary, in order to establish the relation between the two processes definitely. It has been recently asserted by Dr. Crooke that scarlatina often occasions an interstitial hepatitis, which may be the starting-point of a chronic cirrhosis; and it is possible, as the author admits, that some of the children upon whom his observations were made may have previously suffered from an attack of scarlatina.

Concerning the cause of these hepatic changes, the author says that, in its general appearance and microscopic details, the liver in rickets seems to correspond to the type of hypertrophic cirrhosis. The changes in the bile-ducts and canaliculi point indeed to a biliary hepatitis, which is supposed to be caused by a chronic obstruction to the bile. He is inclined, therefore, to believe that a possible explanation of the hepatitis in children who suffer from rickets is to be found in the chronic gastro-intestinal catarrh, which is a constant early symptom in all cases. The involvement of the bile-duct in the general catarrhal condition, and the chronic incomplete biliary obstruction consequent thereon, may be supposed to give rise to an interstitial hepatitis such as described.

THE INHALATION OF HYDROFLUORIC ACID VAPORS IN PHTHISIS.

A CORRESPONDENT writes for information concerning the hydrofluoric-acid treatment of phthisis, about which much has been written of late, in France more especially. The reports as to the efficacy of this remedy are very conflicting, some claiming as high as forty per cent. of cures, others asserting that the inhalations exert absolutely no effect upon the course of the disease, and that the improvement noted in certain cases is owing partly to the better care which the patients under experiment receive, and partly to the renewed hope with which they are inspired.

Some experiments recently made by MM. Grancher and Chautard (*Journal de Médecine et de Chirurgie Pratiques*, July, 1888) would seem to show that the assumed poisonous action of hydrofluoric acid gas upon the tubercle bacillus is far from being a fact. They inoculated several rabbits with the same cultures of bacillus tuberculosis, leaving some without treatment and submitting others to the hydrofluoric inhalations. All the animals died at about the same time, and all presented exactly similar lesions. They then treated the cultures, before inoculation, with vapors of varying degrees of dilution, and the rabbits died as in the previous experiments, the only difference noted being that those inoculated with pure cultures, not previously subjected to the action of hydrofluoric acid, died a short time before the others, and that the rabbits that survived the longest were those that had been inoculated with cultures submitted to the vapors of the undiluted acid. They concluded, therefore, that the direct and prolonged exposure of the tubercle bacillus to the action of hydrofluoric vapor slightly modifies its virulence, but does not destroy it.

These experiments do not inspire much hope for a cure of pulmonary tuberculosis by inhalations of hydrofluoric acid gas, for if the concentrated gas failed to kill the bacillus in a test-tube, it is hardly probable that it can exert any very injurious action upon it when growing within the lungs. It is, nevertheless, possible that the inhalations may be of some benefit by weakening the micro-organisms, and thus aiding the tissues in their struggle against the ravages of the invader.

News of the Week.

Dr. Fordyce Barker, our esteemed townsman, has been a third time honored by the degree of LL.D. First from Columbia College of this city, secondly by the University of Edinburgh, Scotland, and recently by the University of Glasgow. The profession will unite in congratulating him on these well-deserved distinctions.

The Mississippi Valley Medical Association.—The Mississippi Valley Medical Association will meet at St. Louis, September 11, 12, and 13, 1888. Dudley S. Reynolds, A.M., M.D., Louisville, is the President, and John L. Gray, M.D., Chicago, Ill., Secretary.

Polypathy is a new form of quackery which seems to have taken its birth in Michigan. The *Medical Standard* says Drs. Plunkett and Rennie, former professors of the Michigan College of Medicine, have become travelling "Polypathic" advertisers. Their circulars state: "Poly is derived from the Greek word which indicates many, and pathy is the root of the word to which we have affixed homœo, also electro, hydro, etc. Therefore, to be a polypath, you must graduate in all schools of medicine, and the doctors are always pleased to show that they hold these diplomas."

The Rarity of Centenarians.—The number of very old people is really much less than is believed or reported. Doubt exists with some as to whether there exists authentic evidence of any person living to be over one hundred and ten years. M. Lévasseur has recently made some investigations which show the truth of the above view. He states that when the Bavarian census of 1871 was taken, thirty-seven persons stated that they were upward of one hundred years of age. It was found, however, on careful inquiry, that only one of them had outlived a century. In Canada, which has a reputation for the longevity of its inhabitants similar investigations were made at about the same time. Four hundred and twenty-one persons were reputed to be upward of one hundred years of age. The exact age of only eighty-two of them could be ascertained by the authorities. Of these, five men and four women were found to be centenarians. In France the Minister of Commerce has endeavored to carry out a similar inquiry in connection with the census of 1886. The report on the subject states that on examination it was found that, of one hundred and eighty persons declared to be centenarians, sixty-seven were only "believed" to have reached that age by their relatives, who could produce no written evidence in support of the assertion. There were only sixteen persons whose age could be shown to be upward of one hundred by authentic documents. M. Lévasseur believes that there are probably not many more than fifty centenarians in France.

The Brinkerhoff Treatment, as we are informed, is a method of injecting piles with carbolic acid, practised by an itinerant "doctor" in Northern Ohio. It appears to possess no merits peculiar to itself, its local popularity depending solely upon the fascination which irregular medicine exercises over so many ill-balanced and novelty-loving minds.

Naphthalol, or Betol, is a compound of salicylic acid and naphthol, which has been recently brought forward by Sahli as a useful remedy for rheumatism. It is given in doses of three drachms in the course of the day. It has no odor nor taste, and is said to cause no disagreeable after-effects. It has been recommended also in the treatment of cystitis from whatever cause produced.

Sloughing of the Cornea from Cold.—A case of partial sloughing of the cornea is reported by Dr. Kuritzin, due to exposure for nine hours on a Russian steppe driving against a snow-storm. Both eyes were similarly affected, somewhat deep ulcers having formed, in shape and position corresponding to the openings between the eyelids; the other parts of the eyes were scarcely affected at all. The patient, who had never previously suffered from any affection of the eyes, made a good recovery.—*The Lancet.*

Poisoning of a Regiment.—A large number of soldiers in a regiment stationed in one of the French fortifications recently exhibited symptoms of poisoning by belladonna. An investigation undertaken to discover the source of the poison showed that it could not be in the water or wine drunk by the troops, for all the garrison had the same. In the absence of a better explanation, it was attributed to the eating of some unripe potatoes containing solanine.

Society Reports.

CONGRESS FOR THE STUDY OF TUBERCULOSIS.

Held in Paris, July 25, 26, 27, 28, 30 *and* 31, 1888.

(Continued from p. 220.)

(Special Report for The Medical Record.)

Saturday, July 28th—Fourth Day.

The subject proposed for discussion at this session was

THE RACES OF MEN AND ANIMALS CONSIDERED IN RELATION TO THEIR SUSCEPTIBILITY TO TUBERCULOSIS.

M. **Robinson**, of Constantinople, sent a communication on

PULMONARY PHTHISIS IN ASIA MINOR.

Notwithstanding the fact that the inhabitants of this country lived much in the open air, and under the best hygienic conditions, tuberculosis was very prevalent, and ten per cent. of all his patients were suffering from this disease. The natives recognized the contagious nature of the malady and always destroyed the articles used by the sick. The frequency of the disease, there could be no doubt, was owing to the free consumption of milk and of nearly raw meat by the natives.

M. **Solles** read a paper on

HEREDITARY TUBERCULOSIS IN GUINEA-PIGS.

He had watched carefully several litters of guinea-pigs sired by males born of tuberculous parents, but coupled with healthy females. The young were not at first tuberculous, but became so later.

M. **Hanot** related a case of

TUBERCULAR CIRRHOSIS.

The patient was a man, twenty-five years of age, free from malaria, syphilis, or alcoholism. He died of pulmonary phthisis, having suffered also from marked ascites, and at the autopsy the peritoneum was found normal, but the liver was small and marked by numerous furrows. The microscope showed advanced cirrhotic changes. It was impossible to attribute the hyperplasia of the connective tissue to the presence of tubercles, which were absent in the liver, and the author thought it probably due to the action of soluble products secreted by the micro-organisms.

M. **Galtier** sent a communication on

EXPERIMENTAL HEREDITARY TUBERCULOSIS.

He was unable, in nine experiments on guinea-pigs, to obtain a single example of the transmission of the disease from the dam to her young. He concluded, therefore, that true hereditary tuberculosis, if it exist at all, is of very rare occurrence. The young which were suckled by the dam became tuberculous as a rule.

M. **Arloing** said that he had seen a case of

INTRA-UTERINE TRANSMISSION OF TUBERCULOSIS.

A female guinea-pig was inoculated, and two of the young, born ten days later, were found to have caseous masses in the skin.

M. **Robcis** said that, of nearly three hundred autopsies of milch-cows in Paris, he had found tubercular lesions in only three per cent. The disease, in the dairies of Paris at least, would seem, therefore, to be less common than is generally supposed.

M. **Ricochon** read a paper on

FAMILY TUBERCULOSIS.

He said that the early appearance of tubercular lesions in infants was not necessarily an evidence of the hereditary transmission of the disease. In the case of fifty-three individuals suffering from pulmonary phthisis, he had made careful inquiries into their antecedents, and had found tuberculosis in one hundred and eighty-one of the near or remote relatives. In eighty-three there was nervous or mental disease; in thirty-eight, congenital dislocation of the hip; in twenty-eight, cancer; and in thirty-three, rachitic deformities of the bones. Besides these there were numerous cases of varicose veins, hernia, nævi, and various developmental defects. These various affections were an evidence of some structural defects in the osseous and fibrous tissues, notably of deficiency of the mineral constituents, and this excessive loss of the mineral elements was also shown by the examination of the excretions (urine, sweat, and sputum) in those hereditarily predisposed to tuberculosis, which were found to contain an excess of alkaline chlorides, earthy phosphates, lime-salts, etc. The tissues became probably, by reason of this deficiency in the salts, more susceptible to the attacks of the specific micro-organisms.

M. **Ferrand** related the histories of three families, in each of which one of the parents was tuberculous. The other parent did not become affected, but all of the children were diseased.

M. **Malvoz** asserted that

MICRO-ORGANISMS CANNOT PASS THROUGH THE HEALTHY PLACENTA,

for this organ is not adapted to the arrest and detention of pathogenic microbes. The cases of congenital tuberculosis in the records of veterinary practice are very rare.

M. **Cagny** related a case of

TUBERCULOSIS TRANSMITTED FROM MAN TO POULTRY.

The chickens belonging to a certain family, one member of which was suffering from pulmonary phthisis, were found to be almost all diseased. The author learned that the sick man was in the habit of walking in the garden, and it had been noticed that the chickens eagerly seized upon the matters expectorated by him. The chickens had tuberculosis of the liver, and it was found necessary to sacrifice the entire flock.

M. **Jonesco** reported a case of

TUBERCULAR ARTHRITIS,

occurring in a rheumatic individual. It would seem as if the rheumatic affection of the joints had prepared the way for the lodgement of the bacilli of tuberculosis.

M. **Verneuil** said that it had been supposed that there was a sort of

ANTAGONISM BETWEEN RHEUMATISM AND TUBERCULOSIS

He had previously reported hybrid cases similar to that of the last speaker. He thought that in such cases investigation would show that one of the parents had rheumatic antecedents, while the other had sprung from tuberculous stock.

M. **Aguirre**, of Chili, reported the results of his experience with

TUBERCULOSIS IN SANTIAGO.

The mortality from phthisis was twenty-two per cent. of the total mortality among women, and thirty-three per cent. among men. A large proportion of cases were in children, and were the result largely of improper feeding.

M. **Legroux** presented a communication entitled

INFANTILE MICROPOLY-ADENOPATHY AS A SIGN OF TUBERCULOSIS.

It was not uncommon to see, in children between the ages of one and thirteen years, numbers of small, round, movable tumors just beneath the skin, chiefly in the region of the neck. This generalized glandular hypertrophy, which recalled, but was easily distinguished from, the syphilitic adenopathy, was always dependent upon tuberculosis, and those affected with it were at least potentially, if not actually, phthisical. He said that at the last baby-show in Paris, the prize-winner, a fine healthy-looking child, had this multiple micro-adenopathy at the time, and died eight months later from pulmonary phthisis.

M. **Daremberg** confirmed the observations of the previous speaker. He spoke particularly of the fact of the cervical chain of lymphatics being primarily and principally affected. This pointed to the mode of infection in these cases, which was through the tonsils. All of these children had enlarged tonsils.

M. **Leloir** read a paper on

ATYPICAL VARIETIES OF LUPUS.

The first form was characterized by the presence in the skin of small vitreous-looking areas of colloid degeneration. Here and there were minute colloid cysts surrounded by a zone of embryonal cells; there were very few giant cells, and only occasionally was it possible to detect a tubercle bacillus. This he called the colloid variety. In the second form the tubercle was translucent, gelatinous, and very vascular, and small mucous cysts were frequently seen; giant cells were very rare, but the bacilli were seen more often than in the preceding variety. This was the mucoid or myxomatous variety. The third form was denominated

SCLEROTIC LUPUS,

and was a process similar to warty tuberculosis or to fibroid phthisis. The specific micro-organisms are present, but they are extremely rare. These were all varieties of lupus vulgaris, which was but an attenuated tuberculosis.

M. **Bang**, of Copenhagen, read a paper on

HEREDITARY TUBERCULOSIS

in animals. He believed this mode of transmission of the disease was much more common than it is ordinarily assumed to be.

MM. **Hallopeau** and **Wickham** presented a communication entitled

SUPPURATIVE LUPUS,

based upon the report of a case observed by them. The patient was a blacksmith, and, as the disease first appeared in a cicatrix on the chin resulting from the bite of a horse, he thought the disease might be a form of chronic glanders. The skin of the face and the mucous membranes of the nose, cheeks, and gums were involved in an ulcerative process. Bacteriological investigation showed the presence of tubercle bacilli.

M. **Calmette** read a paper on

THE EVOLUTION OF TUBERCULOSIS IN HEALTHY SURROUNDINGS.

His observations were confined to Belle-Isle en-Mer, an island lying eight miles from the mainland. The course of the disease was modified by the healthy surroundings, being very slow. Often the affection would lie quiet for five or six years, then seeming to have acquired more strength, would proceed slowly, without any hectic symptoms. It affected the viscera usually, though sometimes beginning as a broncho-pneumonia. He had obtained good results in the treatment by means of the internal administration of phosphorated oil combined with sea-water.

M. **Arloing** read a paper on the

SUSCEPTIBILITY OF DIFFERENT ANIMALS TO TUBERCULOSIS.

Guinea-pigs, he said, are particularly liable to acquire tuberculosis from inoculation, the induced disease soon becoming generalized. Rabbits, however, which were formerly supposed to respond quickly and readily to subcutaneous injections of tuberculous material, did so with difficulty, and even after the disease had been provoked, the lesions were usually single and scattered.

This paper was discussed by several members, who agreed substantially with the author in his preference for guinea-pigs over rabbits as subjects for diagnostic inoculation.

M. **Valude** then presented a communication entitled

TUBERCULOSIS OF THE SALIVARY GLANDS.

Tubercular lesions of the mouth, he said, are comparatively rare, especially when we consider the large extent of surface in this cavity and its unusual degree of exposure to the action of micro-organisms. An explanation of this immunity had been offered in the supposition that the microbes contained in the saliva were inimical to the tubercle bacilli and hindered their development. He had made a series of experiments to determine the truth or falsity of this theory, and had found that direct inoculations of the different salivary glands were almost invariably successful. The saliva, then, at least the secretion of each gland separately, had no restraining influence on the tubercle bacillus. The immunity of the buccal structures was therefore due, in all probability, to the great number of micro-organisms in this cavity, which, by their continual growth, prevented the development to any undue extent of any one kind.

M. **Jeannel** described, under the name of

ACUTE INFECTIOUS TUBERCULAR FEVER,

an affection characterized by pyrexia without the presence of any local lesions. The diagnosis between that and typhoid fever was often difficult, and indeed it had been asserted that the former was but an engrafting of tuberculosis on the latter. This, however, was not the case. In tubercular fever the temperature rises rapidly, often to from 102° to 104° F. within the first few days, then remains nearly stationary for some days, and finally descends suddenly and irregularly. During defervescence there is profuse perspiration of a peculiar odor, which once experienced can always be recognized. There are no typhoid symptoms, so-called. The difference in character of the two diseases is also shown by the fact that antipyrine has no effect upon the pyrexia of typhoid fever, but exerts a very beneficial influence upon that of the disease under discussion, seeming to conquer it with the same facility and certainty that quinine does malaria.

M. **Thierry**, in speaking of

TUBERCULOSIS IN CALVES,

said that one of the causes for the difficulty of its extermination in regions where these animals were bred for the market was that, in large establishments of this kind, the milk of all the cows of the herd was mixed together before being given to the calves. It was only necessary, therefore, to have one cow with tubercular mastitis in order to infect the whole herd of calves.

M. **Van Hersten**, of Brussels, said that tuberculosis is found in cows in the proportion of four per cent., while among calves not more than one in six or eight hundred is affected. This would appear to demonstrate that heredity plays but a very insignificant rôle in the causation of the disease.

Monday, July 30th—Fifth Day.

At this session the third question, viz.,

THE MODE OF INTRODUCTION AND PROPAGATION OF THE TUBERCULAR VIRUS IN THE ECONOMY,

was proposed for discussion.

M. **Torkomian**, of Scutari, sent a communication in which he described

A TUBERCULAR NODULE OF THE THUMB,

which had developed in his own person in consequence of a prick received during an autopsy made on the body of a man dead of phthisis. The little tumor was removed and no further symptoms were noted.

M. **Verneuil** said that M. Maisonneuve and himself had each had a similar tumor, arising in the same manner and from the same subject. In neither case did any symptoms of general tuberculosis develop.

M. Roussel read a paper on

MEDICAL ANTISEPSIS BY SUBCUTANEOUS INJECTIONS OF ARSENIC AND EUCALYPTOL.

He thought that the most rational mode of introducing antiseptic substances into the human organism was by means of the blood, so that they should not be previously acted upon by the digestive fluids. He had been much pleased with the action of eucalyptol dissolved in vegetable oil, and arseniate of strychnine administered hypodermically. If the bacilli were not destroyed, they were at least weakened. Of one hundred and forty-five cases so treated, thirty-five were apparently cured.

M. Jeannel reported two cases of

INOCULATION OF TUBERCULOSIS.

The first case was that of a lady, who had taken care of her son who had been suffering from pulmonary phthisis. A cold abscess formed in the pulp of the thumb, which was still uncured at the end of eighteen months. The second case was that of a prostitute, who was bitten in the back by one of her companions who was tuberculous. A cold abscess, in which tubercle bacilli were found, developed at the site of the wound.

M. Tscherining, of Copenhagen, related several cases of local tuberculosis following accidental inoculation.

M. Boussakis, of Athens, said that he had seen several cases illustrative of the

CONTAGIOUSNESS OF PHTHISIS.

He had not observed any evidences pointing to an antagonism between tuberculosis and malaria, but had often seen the two affections existing side by side in malarial districts.

MM. Straus and **Wurtz** presented a communication on the

ACTION OF THE GASTRIC JUICE UPON THE TUBERCLE BACILLUS.

Experiments made by them had shown that prolonged action of pure gastric juice upon the bacilli was necessary in order to destroy their virulence. The time required was at least six hours. It was, therefore, useless to expect that the bacilli could be destroyed by this secretion after their introduction into the human stomach. Chickens resisted the action of tubercle bacilli in the stomach much better than man.

M. Landouzy presented a communication on

TUBERCULOSIS IN EARLY INFANCY.

This disease, occurring in infants under the age of two years, differs markedly from the same affection in older children and adults. In babies it tends less to become specially localized, but assumes more of the characteristics of a general disease, the symptoms being chiefly fever and emaciation. As to the question of heredity, he believed that many infants were born with tuberculosis, but that more acquired it through the food ingested. The subject, therefore, of infant alimentation was a most important one, and demanded the most careful study on the part of hygienists.

M. Petresco, of Bucharest, spoke of contagion through the sputum, and the best means of preventing it. The subjects of pulmonary phthisis inoculate themselves by allowing the infectious sputa to enter the alimentary canal. The author had devised a respirator to disinfect the sputum while still in the respiratory passages, the antiseptic substance employed being a mixture of eucalyptol, creasote, turpentine, and iodoform.

M. Jeanselme related several cases of secondary lupus. The affection of the skin had appeared consecutive to suppurative adenitis, and tubercular bone affections.

Dr. Jacobi, of New York, read a paper on

TUBERCULOSIS OF THE THYMUS GLAND.

The gland is most commonly affected in the course of general tuberculosis, but may be diseased primarily.

M. Butel said that

THE TUBERCLE BACILLUS ENTERS MORE EASILY THROUGH THE DIGESTIVE, THAN THROUGH THE RESPIRATORY, APPARATUS.

The same is true in the case of many other diseases. Hence the great part which alimentation plays in the production of disease in children. There were three incontestable facts which were now known to all, viz.: 1. The virulence of the flesh of tuberculous animals. 2. The predisposition of man to tuberculosis, which had doubled since the beginning of this century. 3. The easy entrance of microbes through the alimentary canal.

M. Giorgieri, of Florence, read a paper on

THE HOSPITAL TREATMENT OF TUBERCULOUS PATIENTS.

in which he recommended small pavilions, thorough attention to the disinfection of the wards and of all objects used by the patients, and the care of the sick by attendants who were strong and healthy, and were above thirty years of age.

MM. Cadéac and **Mallet** presented a communication entitled

THE TRANSMISSIBILITY OF TUBERCULOSIS THROUGH THE RESPIRATORY PASSAGES.

They had found by experiments that neither the air in the room nor the breath of phthisical patients was capable of carrying the contagion. They had also determined that inhalation of air containing tubercle bacilli was not productive of tuberculosis, unless the animal was already suffering from bronchitis.

M. Le Dentu reported a case of

TUBERCULOSIS OF THE UPPER MAXILLA,

occurring in a man thirty-two years of age.

M. Guinard related two instances of

PAINFUL AMPUTATION STUMPS IN TUBERCULOUS INDIVIDUALS.

He had amputated on account of tubercular arthritis, taking every precaution to avoid inclusion of the nerves in the cicatrix. Severe pains persisted, and were found to be due to tubercular lesions pressing upon the nerve-trunks above.

Tuesday, July 31st—Sixth Day.

The question proposed for discussion at this session was

THE DIAGNOSIS OF TUBERCULOSIS IN MEN AND ANIMALS.

M. Espina y Capo, of Madrid, read a paper on

THE EARLY RECOGNITION OF PULMONARY PHTHISIS.

The first thing necessary was to obtain a good history, to discover, if possible, the existence of tuberculosis in the family. Mensuration of the chest was of great importance. When the circumference of the thorax at the level of the axilla was less than twenty-seven inches, that at the level of the xiphoid cartilage was not more than thirty-one inches, and the distance between the two nipples was but seven inches, the probability of pulmonary tuberculosis was very great. Further presumptive signs were absence of a clear percussion-note, inspiratory râles, altered respiratory rhythm with prolonged inspiration and forced expiration, a dry and paroxysmal cough followed by a moist one, occasional aphonia, and dyspnœa on exertion. In doubtful cases, where there was spitting of blood, much assistance would be furnished by the sphygmograph in distinguishing between the hemorrhage due to bronchial lesions, and that dependent upon heart disease. Another valuable aid in diagnosis was the thermometer; in a doubtful case an evening rise to 102° or 104° F. was a pretty sure indication of tubercular disease.

M. Arloing read a paper on the

DISTINCTION BETWEEN SCROFULA AND TUBERCULOSIS.

He said that these two conditions gave different results after inoculation, and the latter was often the only means of diagnosing between them. Many cases of cervical adenitis resemble each other closely in their external characteristics, yet they differ markedly in their power of infection. Inoculations made with the products of tubercular ulcers and cutaneous scrofulides were much less uniformly successful than those made with visceral lesions.

M. Nocard said that the previous speaker was correct in his mode of experimentation and in the results obtained, but not in his interpretation of them. They did not show that there were two diseases, but only that there were two forms of the same disease.

M. Verneuil said

THE SUREST MEANS OF DIAGNOSIS IS BY INOCULATION.

Without doubt the seat and behavior of the lesions under consideration were worthy of study, but not every cold abscess was a tubercular one; while, on the other hand, there were seen occasionally supposed acute abscesses which were really

COLD ABSCESSES WARMED UP,

and which were tubercular. The microscopical search for the tubercle bacillus in these cases is often difficult, and is not always productive of results, and the best, most practicable, and surest method was by inoculation.

M. Clado agreed with the last speaker in regard to

DIAGNOSTIC INOCULATIONS.

The best way of making these was by means of a sterilized pipette, introduced with all precautions into the peritoneal cavity. This is more certain than subcutaneous inoculations. The speaker then referred to some observations made by himself upon

THE EFFECTS OF IODOFORM INJECTIONS IN COLD ABSCESSES.

He had examined the pus before and after these injections, and came to the conclusion that the effect of the latter was to destroy the micro-organisms of suppuration.

M. Landouzy said that much could be done in the way of preventing tuberculosis by studying the susceptibility of different individuals. Some were "congenitally bacillizable," others acquired their susceptibility. Small-pox, for example, rendered its victims especially liable to tuberculosis. Of three hundred persons who had had small-pox, but seven escaped phthisis.

THE DIAGNOSIS OF TUBERCULOSIS IN CATTLE

was then discussed by several speakers, most of whom agreed that this was a much more easy matter than the majority of physicians and veterinarians were inclined to believe.

M. Luton read a paper on

COPPER IN THE TREATMENT OF TUBERCULOSIS,

which he recommended most highly. The salt which he employed was the sulphate, and the dose was one-sixth grain, increased in certain cases to three-fourths grain. It was in the early stages more especially that this drug was of the greatest service.

THE THERAPEUTICS OF TUBERCULOSIS

was then discussed by several speakers, the remainder of the time at the disposal of the Congress being devoted to this question. No especially novel modes of treatment were referred to.

The President then put to vote the following propositions, which were adopted as the

SENSE OF THE CONGRESS CONCERNING THE QUESTIONS SUBMITTED FOR ITS DISCUSSION.

1. Boards of health should be empowered to investigate all cases of disease in animals, those which are known to be transmissible to man as well as those which are not yet recognized as of this nature.

2. The Congress expresses its gratitude for the decree which has just been signed by the President of France, placing bovine tuberculosis among the contagious diseases.

3. The seizure and destruction of all tuberculous animals, whatever may be their appearance of health, should be a constant practice.

4. The conclusions of this Congress are applicable to all countries, and should not be considered as referring to France alone.

5. Every effort should be made, by means of circulars, lectures, etc., to warn the laity of the dangers of acquiring tuberculosis by the use of the flesh and milk of diseased animals, and to instruct them as to the best means of avoiding these dangers, and of escaping contagion through various articles used by those sick with pulmonary tuberculosis.

6. Special watchfulness is necessary in the case of dairies, to prevent the contamination of the milk by that coming from a diseased cow.

These resolutions were unanimously adopted.

The next session of the Congress was fixed for the year 1890, and M. Villemin was unanimously chosen to preside at that meeting. The Congress was then adjourned.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 19 *to August* 25, 1888.

Vollum, Edward P., Lieutenant-Colonel and Surgeon. Leave of absence extended two months. Paragraph 17, S. O. 192, A. G. O., August 20, 1888.

Alexander, Richard H., Lieutenant-Colonel and Surgeon. Detailed a member of Board to meet at San Carlos, A. T., August 28th, to select a site for a new post at that place. Paragraph 1, S. O. 44, Division of the Pacific, August 15, 1888.

Smith, Joseph R., Surgeon. Medical Director, Department of Dakota. To inspect Forts Pembina, Totten, Buford, Abraham Lincoln, and Yates, Dak. Ter. Paragraph 4, S. O. 77, Department of Dakota, August 13, 1888.

Heger, Anthony, Surgeon. In addition to his other duties, to attend to the duties of the Medical Director, Division of the Atlantic, during absence of Colonel Charles Sutherland. Paragraph 4, S. O. 170, Division of the Atlantic, August 18, 1888.

Wright, Joseph P., Major and Surgeon. Detailed as a member of Army Retiring Board, Fort Leavenworth, Kan., vice A. A. Woodhull, Major and Surgeon, relieved. Paragraph 10, S. O. 190, A. G. O., August 17, 1888.

Woodhull, A. A., Major and Surgeon. Relieved from duty with Army Retiring Board, Fort Leavenworth, Kan. Paragraph 10, S. O. 190, A. G. O., August 17, 1888.

Ainsworth, Fred. C., Captain and Assistant Surgeon. To proceed to Atlanta, Ga., and inspect the new Army Hospital at that place. Paragraph 18, S. O. 192, A. G. O., August 20, 1888.

Maus, Louis M., Captain and Assistant Surgeon. Having completed rifle practice at Camp S. B. Luce, Fisher's Island, N. Y., to return to his proper station (Fort Schuyler, N. Y. H.). Paragraph 3, S. O. 171, Division of the Atlantic, August 20, 1888.

Owen, W. O., Jr., Captain and Assistant Surgeon, Fort Leavenworth. To report for temporary duty to the Commanding Officer, Fort Gibson, Ind. Ter. Paragraph 1, S. O. 104, Department of Missouri, August 20, 1888.

Mason, Charles F., Assistant Surgeon. Ordered to Fort Washakie, Wyoming Ter., for duty. Paragraph 5, S. O. 190, A. G. O., August 17, 1888.

ELECTRICAL TREATMENT OF UTERINE FIBROIDS, WITH ANSWERS TO OBJECTIONS AND CITATION OF NOVELTIES.[1]

By G. APOSTOLI, M.D.,

PARIS, FRANCE.

GENTLEMEN: Every therapeutical innovation which runs counter to prejudices and interests meets with opposition, and has to bear the brunt of hastily formed opinions. This has been the lot of my electrical treatment of uterine fibroids, and I am happy that it should be so, since frank and loyal controversy will bring light upon the subject and strengthen my position.

My first object to-day is to bring forward all the arguments that have been set up against my system, to reply to them, and to show that this can be done with success. In order to avoid personalities and to keep this discussion on a footing of scientific courtesy, I shall group these objections without regard to the source from which they come, and let my reply immediately follow the statement.

In the second part of my paper I propose to introduce to your notice some additions I have made to my therapeutical expedients, which will be regarded as of practical importance.

PART I. ANSWERS TO OBJECTIONS. I. CRITICISMS ON THE BOOK OF DR. CARLET.—Many deprecatory remarks have been made upon the histories of my first hundred cases, as reported in the thesis of my assistant, Dr. Carlet. I must notice them separately.

A. It is said that I have confusedly mixed up cases of simple subinvolution, or the enlargements of chronic metritis, with those of fibrous tumors. How could this possibly happen? since the greater part of the women had never been pregnant, and among the rest I had to deal with wombs of enormous size, some even rising above the umbilicus; besides, the most careful examination, both external and internal, combined with hysterometry, left no doubt in my mind as to the nature of the cases. But even supposing a mistake had been made in some rare cases, it could be no cause for regret, for it would only prove that two conditions, chronic metritis and fibrous tumors, equally refractory to ordinary management, are amenable to the same treatment.

B. Judging by the uterine measurements given in my book a large proportion of my cases have but slightly diminished.—It may be true that in many instances the uterine measurement has but little altered. The sound only gives information as to the uterine cavity. The greater part of fibroids, both subperitoneal and interstitial, may coexist with a nearly normal cavity, and consequently may and have undergone reduction without any appreciable modification of the depth marked by the sound. But independent of this question of anatomical change, variable according to the situation of the tumor, we have to look at that of the symptomatic cure, here the most important. For how often do we meet with considerable fibroids of which the bearers have no consciousness, while the lives of other women are put in peril by small and even the smallest tumors. What is it that brings women with fibroids to the consultation-room? Generally because they have pain or hemorrhage. Why are they operated on? Always for the same reason, to save them from the consequences of pain or hemorrhage. Cavil as much as you please about the importance of such anatomical reductions as I have obtained; but so far as concerns the symptomatic cure there can be no doubt, for I affirm that the greater number of my patients have been made and remain well. Is there any other known method of treating these affections of which so much can be said?

C. Many of the reports of my cases are incomplete.—No one knows better than myself that it is so. If I have nevertheless persisted in including these cases in my statistics, it has been with the plain intention of giving a complete view of my practice, so that an opinion might be formed from it of the harmlessness of the electrical treatment which I have introduced.

D. The treatment is long and troublesome.—This I am so well aware of that since the year 1884 I have made every possible attempt to shorten it by increasing its efficacy. It is with this motive that I have gone on gradually augmenting the intensity of the electrical current, and have made many alterations in my mode of procedure. It will be seen, too, in the new series of cases, under treatment since 1884, which I have almost ready for publication, how marked is the progress made, in all respects, since the commencement of practice.

II. MY METHOD IS ONLY AN OLD STORY, AND MANY OTHERS HAVE ATTEMPTED THE CURE OF FIBROIDS BY ELECTRICITY BEFORE ME.—There is some truth here. But one may observe about the same difference between former applications of electricity and my method as would be found between the ancient theriacal quackery and modern therapeutics. Electricity has been used; but what electricity? in what dose? where? how? for how long and how often? All this is unknown and all was empirical. Over and above the many indications I have scientifically established as to the technique itself, the mode of operating, the electrical localization, the choice of poles, the acquired tolerance of the indifferent or inactive pole, there is one fact which gives me a right to claim priority, and that is, that no one before 1882, or before me, had taken an exact measure of the current he employed, or had employed an intensity of power known to be above fifty milliampères.

III. MY METHOD IS DANGEROUS, AND THE DANGER ARISES IN VARIOUS WAYS.—*A. From the intra-uterine application. B. From the making of galvano-punctures. C. From the use of high intensities of current.*

I have been reproached on account of several recent deaths said to be directly attributable to my treatment. To this indefinite assertion I again give the most positive denial, as I did last year in publishing my complete statistics. I prove, too, by figures relating to nearly seven thousand galvanic applications, the innocuousness of my method provided the operative conditions are appropriate, that it be used rationally, and with antiseptic scrupulousness. I will say a word on each of the three sources of danger specified.

A. The intra-uterine cauterization, which is nothing more than a therapeutical hysterometry, might have appeared formidable before the common adoption of the practice of intra-uterine raclage. As that which I do is only a sort of galvano-chemical raclage, there is every reason to regard it as equally beneficent in its action, and my experience more than fully justifies its *à priori* sanction.

---

[1] Paper read at the Congress of the British Medical Association, Glasgow, August 8, 1888

B. I put entirely out of the question all abdominal or suprapubic punctures. Any one who is not both gynecologist and electrician might be expected to set down the vaginal galvano-punctures as hazardous. In making them we certainly do come within the risk of doing mischief, which must be guarded against, and which my experience enables me to disclose with exactness.

a. It has been urged as a point against my treatment, that after a number of punctures, when there is free suppuration, or a quantity of necrosed matter in the womb, or in the centre of the tumor, there must be difficulty in keeping off septicæmia. This objection would have some force if there were neglect in following the rules which I have framed, viz.:

1st. To observe a constant and perfect antiseptic practice.

2d. To make the punctures only every eight or fifteen days, so as to avoid accumulations of fetid matter; with temporary suspension of the sittings as soon as there are any threatenings of fever.

3d. To make, without exception, only superficial punctures, not more than half, or, at most, one centimetre deep, so as not to cause any central gangrene, and to admit of an incessant antiseptic treatment.

b. Perforation of the bladder or rectum, followed by fistula, and the wounding of some great blood-vessel, are accidents to be apprehended. I admit that a misfortune of this nature happened in one of my early operations. I now point out the way in which it may be avoided.

1st. Never make a puncture in the anterior cul-de-sac.

2d. Confine the punctures to a lateral, or to the posterior, cul-de-sac.

3d. Make use of a very fine trocar.

4th. Never introduce a speculum through which to make a puncture; and before proceeding to puncture make a minute and scrupulous examination of the part chosen for puncture.

5th. Puncture as near as possible to the body of the uterus, from without inward, making the axis of the instrument correspond with the axis of the organ.

6th. Choose for the seat of puncture the most prominent point of the tumor found in the vagina, making it project more, if necessary, by directing an assistant to press it downward with his hands upon the body above the pubes.

7th. First pass the insulating celluloid sheath through the vagina, and fix it at the spot to be punctured, on the point of the index-finger. Then slide the trocar up the sheath and make the puncture.

c. The high intensities, which I have been falsely represented as using exclusively and abusively, are denounced as sources of danger; and the less tolerance shown by rabbits' than the human uterus, under a galvanic current, has been made the base of an objection. As regards the animal, it affords no grounds for comparison. As regards woman, clinical observation has more than sufficiently proved the perfect impunity with which high intensities can be supported; and more than that, it has demonstrated their utility by establishing the fact of the progressive rapidity with which improvement takes place in proportion as the ascending force of the current increases, if it be well applied and well tolerated. I ought, however, to add that there is a limit to this increase of intensity; and it must be regulated by the therapeutical effect obtained. For the present, I disclaim all participation in recommending what I regard as the abuse of those intensities—such as the administration, said to have been made, of currents of more than five hundred milliampères. Moreover, I feel some difficulty in believing that men, who daily put women under the perils of castration or hysterectomy, are speaking seriously when they denounce my procedures by recounting a series of hypothetical dangers.

IV. MY METHOD IS NOT EFFICIENT.—This objection is presented in a variety of forms:

A. For some, it is useless in the greater number of cases.

B. Others say that the current has no action on fibrous tissue; that its effect is only shown on the uterine tissue.

C. Others, again, if they admit any action, say that it is only temporary and ephemeral; that the tumor against which we direct it remains just as it was, and that relapses are sure to come. I answer:

A. The faults committed in the application of the treatment when it is done badly or incompletely, the neglect, in fact, of all the instructions I have given, ought in no way to bring disparagement upon the method itself. Further, I affirm again, as I have already written, that the method properly used has effected, ninety-five times out of one hundred, not, as I have been erroneously made to say, the absolute removal of the tumor, but:

1st. An anatomical diminution which does not advance so far as the complete dispersal.

2d. The quick and lasting cessation of hemorrhages.

3d. The disappearance of all the symptoms of compression.

4th. The symptomatic restoration of the patient.

If these four clinical results are not witnessed regularly, and in the same order, in all subjects, the fact may be explained in many ways. I will mention some of the chief.

1st. The anatomical regression generally varies, first, according to the character of the tumor, whether soft or hard, being more rapid in the case of soft tumors than in the hard ones. Then, again, a difference is made by the situation of the tumor, the localization of the electric action. The more distinctly this is subperitoneal the weaker will be the influence of the current. But without doubt the general tendency of all fibroids, when skilfully treated with high doses of electricity, is toward spontaneous enucleation, by their disengagement from amidst the uterine stroma. This curative process, which consists in their liberation either through the mucous membrane or the peritoneum, is seen to take place with some interstitial fibroids.

I ought, also, to note here what I have almost constantly observed as the treatment advanced; namely, the occurrence of an accumulation of adipose tissue under the abdominal tegument. This new condition ought always to be borne in mind when estimating the size, or changes of size, in fibroids, by measurement of the circumference of the abdomen. The external measurement, even with a collapsing fibroid, may remain the same simply on account of the recent, and often abundant, quantity of fat developed in front of the tumor. I therefore recommend that, at the commencement of every course of electrical treatment, three measurements of the body should be registered, which may serve for future reference: 1st, The circumference of the abdomen at several points; 2d, the exact thickness of the layers of skin and fat, above, below, to the right and to the left of the umbilicus, taken by means of a graduated compass; 3d, the weight of the patient. I cannot deny that I have in some rare cases been disappointed and failed, the same as happens in all human undertakings. The future may enlighten us about these difficulties, for they all relate either to ascitic fibroids or to fibro-cystic, or to abnormally vascular fibroid tumors. I may add that while certain fibroids shrink without any sphacelation, or any appreciable sero-purulent discharge, others only undergo this change as the result of a more or less extensive necrosis.

2d. The arrest of hemorrhage has also been disputed. Many who hold this opinion do so without ever having made, or seen, an experiment on some tissue to convince themselves of the hæmostatic power of the condensed action of the positive pole, when applied to a cut and bleeding surface. Then, I am asked to explain how it is that results are not constant. I can only say that this depends upon different conditions, clinical, anatomical, and physical. Clinically, hemorrhages are more difficult to suppress in the cases of interstitial and submucous fibroids. Anatomically, the arrest of hemorrhage will be more speedy and certain as the uterine cavity is more narrow and less deep. Physically, the hæmostasis becomes more decided as we augment the intensity of the electrical current, and insure the perfect coaptation of the electrode with the entire extent of the bleeding surface.

To resume, the arrest of hemorrhage by electricity is arrived at in three different ways, either associated or independent of each other. The action of the current, which is a vehicle of force and of chemical action, may be studied either as it is manifested at the poles, or in the interpolar circuit.

a. The polar action of the positive pole is hæmostatic, either at once, or some time afterward: Immediately, if the bleeding surface is totally cauterized by the application of a sufficient intensity; subsequently, after some interval from the commencement of the treatment, if the hæmostatic action has not been powerful enough in the first instance, by the appearance of an atresia, more or less pronounced, of the uterine canal. This atresia, which some gynecologists will not admit, I have the opportunity of seeing almost every day in some one or more of my former patients, although they have not yet arrived at the menopause. In certain women, with a large uterus and an expanded cavity, in which the ordinary sound had moved with great freedom, I have discovered one, two, or three years afterward, that it could not then be introduced, and that the canal only permitted the entrance of a sound of the most diminutive size. Now, this cicatricial atresia (which, however marked it may be, and as a new observation it is interesting to notice this, is not accompanied with dysmenorrhœa) is the physical reason of the postponed electrical hæmostasis, and of the permanence of the results established.

b. The interpolar action is equally hæmostatic in a tardy manner, and in an entirely different way, without the polar action being in any degree implicated. Indeed, there is reason to believe that we may stop hemorrhage, though it must be confessed more slowly, without at all cauterizing the mucous membrane, and by restricting the treatment to galvano-punctures made in the tissues of the tumor itself. The denutrition of the substance of the fibroid will, after a certain time, bring about a progressive stoppage of the hemorrhage, without the mucous membrane having been touched. Either pole may be used for this purpose, though I incline to prefer the negative. It is more to be relied upon because it is more denutritive than the positive. I have, as a matter of experiment, given clinical demonstration of this separate interpolar hæmostatic action, by treating several hemorrhagic fibroids by galvano-punctures only, without any intra-uterine cauterization. I am convinced, however, that the combined use of the two methods will be found more certain in producing the hæmostatic action, in cases where the simple intra-uterine cauterization has shown itself ineffectual.

3d. The cessation of pain and of the effects of compression will vary among patients as much as the causes which produce them. Generally, this takes place coincidently with the retrogression of the tumor. In other instances, on the contrary, it is the initial phenomenon which precedes all others. This may be accounted for either by the relief of the uterine congestion, which is early realized, or by the mitigation of the ovarian neuralgia. There are cases, however, in which this amelioration comes on but very slowly. I have remarked that in these inveterate cases we can generally recognize some ovarian or tubal complication, some inflammatory or suppurative condition of these parts, which is less disposed to yield to electrical treatment.

4th. The symptomatic restoration of the patient is the most striking result of the treatment, the most rapid, and that which most surprises both the subjects of it and their medical attendants. One of the few adversaries of the method has thus expressed himself: "I have been able to assure myself that all the women under treatment have experienced a stimulating influence, very favorable to general nutrition and the recuperation of their forces. They feel more cheerful, more buoyant, more alert; in a word, seem to have more life. Whether it be that the innervation, sensibility, and mobility of the abdomen and pelvis are more happily excited, the patients keep about without difficulty, and walk freely, in a way which was impossible before anything was done for them. The movements are unembarrassed. The tumor no longer distresses by its weight, or contact with the sensitive viscera. With the trunk and the pelvis disengaged from an overpowering constraint, the limbs do their office with freedom." They acknowledge, too, that the digestive functions are well performed, that sleep is natural, that the miseries of bladder pressure have ceased, that constipation is less annoying, and that there is a restoration of active life in all its integrity and intensity.

B. The second reproach of inefficacy is made on the supposition that the current can act only on fibrous tissue and that it has no effect upon the uterine tissue. There is falsity in this limitation of the effect of the current; and the proof is that an action, combined or isolated, may be observed in both one and the other of these tissues. We see cases, in fact, where the uterus itself undergoes no contraction, as may be ascertained by the sound, while examination above the pubes enables us to decide positively as to a diminution of the subperitoneal part of the fibroid tumor. On the other hand, in the simple hypertrophies which follow chronic metritis, or in the non-fibroid hypertrophies of the uterine tissues, there is always a lessening of the uterine cavity under treatment. The action, then, is here only on the uterine tissue, as in the other case it was upon the fibrous tissue; and the process of disintegration, set up by the passage of the current, results in promoting a general retrograde metamorphosis of the muscular, connective, and fibrous hyperplasias.

C. The third reproach, in reference to inefficiency, which consists in a declaration that the effect of the treatment is only temporary and ephemeral, can be no better sustained. It is now six years since I began the practice of this method, and I have regularly and carefully kept an account of the condition of my patients. I can affirm that relapses have been truly exceptional. The very infrequent cases where I have had to administer secondary treatment were those of women who had unadvisedly discontinued their attendance. There has been no difficulty in bringing this secondary treatment to a satisfactory end.

V. My Method is Empirical and Unscientific.—It is said that it wants precision, and that I have given a theoretical explanation of it which cannot be admitted. If my method be empirical, it stands, in that respect, on the same level as the whole of pharmaceutical practice; empirical as the giving of opium which causes sleep, empirical as the use of quinine and digitalis to check fever or modify the circulation. The why and the wherefore of things elude us. What we have to do is to make ourselves familiar with the natural laws ruling the phenomena which come before us. Every organic or inorganic movement, every molecular change excites a corresponding development of electricity, and the process of nutrition, like every other vital action, is subject to this law. Now a continued current passed through the human body marks its presence in two different ways. At the points of entry and exit, that is, at the two poles, in virtue of an electrolytic action inseparable from the passage of the current, we find an accumulation of acids on one side and of bases on the other. This is a fact commonly known, and I shall have to refer to the therapeutical importance of these acids and bases. In the organic substance intermediate between the two poles, the interpolar region as it is called, through which the current spreads in rendering itself from the point of entrance to that where it is discharged, there is a twofold action. The one is contemporaneous with the current itself, the other is posthumous. The contemporary action consists in an exaggerated vital and circulatory activity, favorable to the rapidity of nutritive changes. This will explain the absorption of certain effusions, either interstitial or intra-articular, under the influence of a current directed through them. The posthumous action, enduring after the cessation of the current, occasions that condition known as the polarization of the organic tissues. This is an accepted fact. The organic region, thus occupied by the circuit of the current, is in effect charged as a second battery. It is consequently endowed with a supplementary electro-motive force or tension, which in its discharge prolongs the topical and trophic effects that the preliminary current had begun; and it still further advances the retrograde metamorphoses which we see in non-malignant neoplasms. Yet we encounter some who say that there is no such thing as interpolar action, and that the current leaves no visible or tangible trace of its presence. Who has ever been eye-witness of a current in a nerve-trunk? Who has ever seen the something which is transmitted by the telegraph wires? As it is with many natural phenomena, such, for example, as nutrition, which we only know by its effects, so it is with the current. Let anyone who denies the fact of interpolar action but just apply one pole to the forehead and the other to some part of the body, the hand or foot, and he will at once have sensory evidence of two phenomena which constantly follow: First, the appearance of flashes of light, and secondly, a change in taste of the saliva. How should we account for these invariable phenomena, unless there be an interpolar action of the electric current? Place one pole on the neck, over the pneumogastric nerve, and let the other be held in the hand. You will thus stop many a threatened vomiting. It must be some interpolar action which produces this effect. Indeed, nervous pathology as a whole (nervous, medullary, cerebral, or peripheral) requires ordinarily nothing more as a means of relief than the interpolar action of the continued current. If interpolar action were not a reality, electro-therapeutics would soon become an idle word, for it would be reduced almost to the simple chemical or mechanical effects of polar action; and these we might in a great measure afford to neglect. As we recognize this sceptically treated interpolar action by its unavoidable consequences, so we have, as evidence of its presence, the effects of polar action. On this point, again, I am accused of empiricism; and my accusers merely substitute their erroneous interpretations of the respective action of each pole for the formulas that I have laid down. I have said the negative pole is more irritating, more charring, more destructive than the positive pole. In opposition, I am told that as acids abound more in the human tissues than the bases, we ought to find a greater proportion of acids at the positive pole than of bases at the negative pole; hence the preponderant action, quantitative, of the former. But the fact is overlooked that a current has no caprices, and acts only according to the laws of its nature; that electrolysis or decomposition takes place molecule by molecule, equivalent of acid for equivalent of base, whatever may be the composition of the body under experiment. The only preponderance which one pole has over another is purely qualitative. The dry, positive eschars offer a considerable resistance to the flow of the current, and consequently impede its diffusion. The negative eschars, on the contrary, are softer and more moist, and, only feebly opposing the current, allow of its more easy dispersion. There is no difficulty in convincing one's self of this fact. Take two electrodes of equal dimensions, of gas-carbon it may be, covered with moistened leather, and place them symmetrically on two parts of the body. Of the two poles it is the negative which will first give indications of its activity by the pain it occasions, the eschars and the extent of the eschars which it burns. In the same way after punctures with two trocars actually of the same character, the loss of substance resulting from the fall of the eschar, made by the negative pole, will be much more considerable.

In conclusion, if the electrolytic action is found to be concentrated at the two points of entry and outlet of the current, it is impossible to deny the intermediate dynamical action, which is more powerful than either. It matters little for our purpose whether this intermediate action be directly upon the tissue-cells, or, which is more probable, upon the nervous influx of which it augments the tension, as auxiliary to the normal currents in them. The clinical results are incontestable. There is the same retrogression of fibromes that is often found to take place after the menopause, or the excision of the ovaries, without our being able to furnish any unimpeachable theory to account for the facts.

VI. My Method is of no Use, and there are Better Ways of Treatment.—Let us consider the worth of these other modes of getting rid of fibroid tumors.

A. Mere expectation, or literally doing nothing, aided by repose in bed, is sometimes trusted to as sufficient to assure the retrogression of the tumor and the quiet existence of the patient. This can only be true of a few fibroids, especially after the change of life. But it will not do to lay down an absolute rule, based on these particular cases. Every day's experience shows us that the death of a great many women is the consequence of their tumors, and that others, in large numbers, have their lives embittered by pain and hemorrhage. I admit that some, under the influence of confinement to bed for several months, find a temporary amendment, but I cannot see that this enforced rest ever produces a spontaneous and regular diminution of the fibroid and the disappearance of the symptoms, such as follow the use of my method. Nor can it be maintained that similar improvements under my treatment are mere coincidences, for my patients are not kept in bed, continue their ordinary occupations, mostly come for their sittings to my consulting-rooms, and follow the common mode of life. I believe that much more is to be expected from the influence of the menopause alone, although not as a matter of course; for I have had under my care not a small group of women from fifty-five to sixty-five years of age, who had experienced the disappointment of finding their tumors enlarged considerably, and even doubled in volume, after the menopause.

B. Then it is said that treatment by medicines will give relief and is equal to the cure of fibromes. This assertion will not bear examination. The very multiplication of the remedies eulogized is a proof of their powerlessness. What, in fact, do the recommendations amount to? As for mineral waters patients may go on using them, hopefully and unprofitably, year after year till they arrive at the time of the menopause. Internal medication is very uncertain, and for the most part untrustworthy. Ergot stands at the head of the list of things tried. Independently of the local and general mischief of which it may be the cause, it must be allowed that it more often fails than succeeds. Women come to me showing the marks of ergot injections, to which they had patiently submitted for years, without any perceptible benefit. Before the adoption of my electrical method, one other kind of treatment only had been at all encouraging; it was that of A. Tripier, who places in the uterus pencils of a paste of iodide of potassium.

C. Next, surgery claims the precedence of medicine. First of all there is the minor surgery, which includes intra-uterine raclage, liquid injections, and punctures with the actual cautery. However excellent may the use of raclage in simple endometritis, its sphere of action is limited to the mucous membrane. It has no power over lesions of the parenchyma, none over fibroids. Nothing better can be said of liquid injections. They, too, have special dangers by no means insignificant. As for vaginal cauterizing punctures, their effect is deceptive and temporary. Their action in no way corresponds with that of the galvano-chemical punctures which I employ. These two modes of puncturing have, in fact, nothing in common but the name. They are essentially different. In a cauterizing puncture, even when it is a galvano-thermic cauterization, heat is the agent upon which we depend.

There is no special electrical action. The platinum wire. brought to incandescence by the current, burns and burns only. It conveys no current into the tissues, which are simply cauterized. On the contrary, with galvano-chemical punctures, we have both a local chemical action and a general dynamical action, but no effect of mere burning. The electrical current, going from pole to pole, inevitably traverses all the tissues upon which we intend to operate.

We now come to surgery proper, which assumes to have settled the question magisterially. The exploits of ovariotomists have given a new character of boldness to abdominal surgery. In urging operations, the risk of the life of the patient has been sometimes too lightly considered. In spite of its difficulties, its dangers, the long convalescence which it involves, and always with the presumption that antisepticism will come to aid in lessening the mortality, abdominal hysterectomy has been by some hands pushed too far. To go no further, for figures, than Paris; our Surgical Society has recently published a statement showing that, according to the operators, the deaths from this operation mount up to from forty to fifty per cent. If left to themselves, do patients die at this rate from their tumors? And have we not reason to assent to what Thomas Keith has said, that "abdominal hysterectomy has done more harm than good?" We see, as a consequence, a general disposition to substitute the vaginal operation for that which has been so fatal. True, the loss experienced is smaller, but then comes the drawback of its being practicable only at the early stage of growth; for I maintain that it would be impossible in the case of large tumors. Operative failure in this direction has led many surgeons to discard hysterectomy for the cutting away of the uterine appendages; the intention being to give women the supposed advantages of an induced menopause. But even here there is no guarantee of constant success, for every operator has been obliged to record not only inadequate results, but some cases of death. It therefore becomes a serious matter for consideration, whether, as a point of professional morality, one is not bound to make trial of a system of treatment which I and others affirm to be not only harmless, but effective, before recommending a patient to take the risks of hysterectomy or the certainty of mutilation.

VII. My Method Wants Exactitude and is Uncertain in its Effects.—It has been objected that, however easy it may be to graduate the intensity of the current, and consequently to estimate the equivalent of acid and alkali set loose by its passage, there must always remain an undetermined free residue capable of effecting further cauterization after saturation of the uterine secretions. Thus uncertain excess of cauterizing material is a bar to anything like precision in your procedure. I meet this objection in two ways, by pointing out, first, the mistake made in confining attention only to the polar action; and, secondly, that a wrong idea is formed of the nature of electrical cauterization. This is of primary importance. While ordinary caustics, whatever be their composition, act from without inward at the point of contact, and, after a time, form in the products of mortification a barrier to any more profound penetration, the galvano-chemical caustic acts in a different manner, by setting up a kind of auto-cauterization. The tissues are decomposed by the electrolytic action of the current, and the resulting products are the cauterizing agents. The character of the eschar thus formed is in exact relation to the intensity of the current and the duration of the operation. No acid or basic product is left disengaged, and the tissues cauterize themselves continuously from the beginning to the end of the sitting, without any other limitation, interruption, or suspension of the action, except that which comes from the will of the operator. This cauterization encroaches more and more on the deep layers of tissues, instead of being restricted to the surface, and ending, as imagined, in the disengagement of acids and alkalies in the uterine cavity.

VIII. My Method is Difficult, Costly, and Troublesome.—So far as regards difficulty, there certainly is less than with hysterectomy. I want no assistant, can operate anywhere—at the home of my patient or in my own room, and though the operator must be both gynecologist and electrician, the scientific qualifications are easily acquired. When one has to pay the enormous price demanded for a complete laparotomy equipment, it seems absurd to quibble about four hundred or five hundred frances, the cost of electrical apparatus. It will be seen that the trouble of transport and management dwindle to a mere trifle, when I am able to announce that, at my suggestion, the electricians in Paris are now making perfect batteries, which take up very little room and are quite transportable, the cost being one hundred and fifty or two hundred francs.

IX. My Method is Imperfect.—Here the objections are both to the apparatus and instruments I employ and to the way in which I use them.

A. The apparatus.

1st. The galvanometer of Gaiffe.—Some call it a toy; others say it is not to be depended upon. I have used this instrument for some years and have made my own observations upon it; and I have had it, and others, submitted to the opinion of competent electricians. We find that the galvanometer of Gaiffe is the only one in which the graduation is exact. By testing, I can find an error in the record of only from two to three per cent., which is of no practical importance. It also has the merit of being cheap. Edelmann's galvanometer without "shunt" fails to the amount of 7.05 per cent.; with "shunt" the defect increases to twenty per cent. It registered $\frac{160}{1000}$ ampère, instead of $\frac{200}{1000}$ ampère. An American galvanometer by Waite is of the same construction, and has the same faults as the German instrument. The constants are:

without shunt,		error	6	per cent.	at least.
with	" 10 —	"	32	"	"
with	" 100 —	"	25	"	"

In face of these plain physical facts all theoretical complaints must give way.

2d. The hysterometer in platinum.—Objection is made to its being straight and rigid; and it is proposed to replace it by a sound made of copper which will bend easily and accommodate itself to the passages. Any one who is in the habit of passing a sound, as it ought to be done, without the speculum, will give preference to a sound which is rigid: *a*, Because it enters more readily; *b*, because we can more easily change its position in the uterus; *c*, because it can be made to pass more easily over any obstacles, especially about the internal orifice. Another sound, made of platinum wire coiled round a stem of copper with a point of caoutchouc, has been recommended instead of mine. The insulating end of caoutchouc is bad, since it stands in the way of complete cauterization. The wire also is wrong in that it does not make a good conductor, is kept clean with difficulty, and with so many interstices can scarcely be made aseptic. The sound is too flexible and does not preserve its polish.

3d. Dirty, cold, and troublesome.—Such is said to be the pad of clay which I place upon the abdomen; assuredly I should be pleased to find something better. I have tried several of the substitutes which have been proposed for the clay, but have found none of them to have the same quality of plastic adaptive adhesiveness. Neither do they well guard against the burning of the skin. The women, therefore, have more pain and are more scarred, as I observed in London. The abdominal electrode of Franklin Martin, of Chicago, is the best I have met with, and will perhaps be adopted. It gives us the opportunity of applying it to the abdomen at an agreeable temperature.

4th. The insulating sheath of celluloid.—In exchange for this, we are offered sheaths made of gum elastic, such as used for catheters. which is corroded by many solutions and tears readily. I cannot find that it has any of the qualities of the celluloid which I introduced. This substance insulates perfectly, is aseptic, hard, easily cleaned, durable, not injured by acids, can be plunged, if necessary, into boiling water, and has only the disadvantage of being inflammable.

B. Technique.—For some curious reasons, which I cannot understand, there has been a sort of jealous rivalry in changing the details of my practice.

1st. In regard to intensities.—Some have talked of using currents of five hundred and one thousand milliampères. Now this would be dangerous, and I should say impossible; impossible certainly without chloroform, for in all my experience I have never seen a woman on whom such a dose could be tried—dangerous for the safety of the skin of the abdomen, which must be burned, and from the general mischief which would follow the operation. But knowing the little reliance to be placed in the greater part of the galvanometers in use, I look upon all these reports of excessive intensities as exaggerations.

2d. Dosage uncertain.—As I am supposed to have been rather loose in my dosage of electricity, it has been thought proper to call in the aid of mathematics to regulate matters for all sorts of cases, but especially for bleeding cases. An experiment is made showing that a current of twenty-five milliampères intensity, traversing a positive electrode of platinum, with a surface of one square centimetre, and applied for five minutes to the mucous membrane of the neck of an enlarged uterus, will so condense the structures that no further bleeding can take place, even when they are punctured to the depth of one and one-half centimetre. Hence, it is concluded that success must follow as a constant consequence if we maintain the demonstrated proportions between dose and surface; and it is laid down as a rule that we are to use a current of fifty milliampères for an electrode of two square centimetres surface, and of one hundred milliamperes for one of four square centimetres. This may sometimes turn out to hold good, but not with the precision announced. For who does not know how many sources there are for these hemorrhages; lesions of the mucous membrane, lesions peripheral: *a.* Lesions of the mucous membrane. These vary in extent and depth, in the condition of the blood-vessels, and in the amount of congestion. *b.* Peripheral lesions; such as reflex hemorrhages, hemorrhages connected with the evolution of intra-parietal neoplasms, passive hemorrhages due to disturbance of the peri-uterine circulation, hemorrhages depending upon some affection of the tubes or ovaries. It is evident that, setting aside simple lesions of the mucous membrane, the dosage of electricity, in its application to uterine diseases, must vary according to the circumstances of each case. I believe that the general instructions I have given from experience will serve to guide through most difficulties: Use for a bleeding fibroid the highest intensity of intra-uterine current a patient can bear; if that does not answer, add punctures to the cauterization; should they not be sufficient, put the patient under chloroform and raise the dose.

Such, gentlemen, are the objections made to my method, and such are my answers. I consider my answers perfectly meet the objections. But there is one fact which overrides all verbal quibbles and theoretical irrelevancies. As regards my method, gynecologists muster in two ranks; those who have tried it, and those who have talked about it. The practical men give me their adhesion, and with that I am satisfied. The talkers have had their say, and one of your English proverbs, "An ounce of practice is worth a pound of theory," is enough for them.

PART II. THE NOVELTIES IN MY METHOD OF TREATMENT.—Having thus, so far as I am concerned, cleared the ground of controversy, I pass on to clinical and practical questions. I am far from supposing that we have reached the last stages of the development of the electrical treatment of fibroids. Some modifications, which I proceed to explain, will, I think, be found to mark a decided progress. The two dominating symptoms in these cases are pain and hemorrhage. I will give them separate consideration.

I. PAIN.—I need not enter into details as to the many sources of this pain; it may be either concentrated in the uterus itself, or diffused. We have: 1st. Localized uterine pain, arising from an augmenting interstitial compression, such as is often complained of during the early period of growth, without there being any appreciable bearing upon the neighboring nerves or organs. 2d. Extra-uterine pain, which may depend upon a not uncommon, but often oversighted, partial perimetritis or parametritis. We meet with inflammatory conditions of the appendages; and sometimes with uncomplicated ovarian neuralgia. To relieve this symptom, pain, the almost uniform gynecological solicitude, we have, as I was the first to point out, a powerful resource in faradization. The currents of tension, applied as much as possible in the cavity of the uterus, and under the conditions which I have for some time indicated as to electrodes, and especially the duration of the sitting, are sedative in a high degree. They will be found of almost certain arresting power in simple ovarian neuralgia; calming only in cases of pain from other sources, and of but very little service in the acute and suppurating forms of peri-uterine inflammation. We have then, in my opinion, a most energetic agent with which to encounter this element of pain, in cases of fibroid tumor, in the judicious association of induced and continued currents, under the form of an intra-uterine galvano-chemical caustic. But we are not restricted to the use of these means only. For we have in such cases a supplementary expedient in galvano-puncture, or the direct transmission of a current through the substance of a tumor, using for this purpose the negative galvano-puncture. We may perhaps account for the good effects observed, by the rapid retrogression of the tumor, or in the setting up of a more powerful derivative action. Explicable or inexplicable, the clinical fact remains undeniable, that many of my cases of painful fibroids have been put at ease by the negative galvano-punctures.

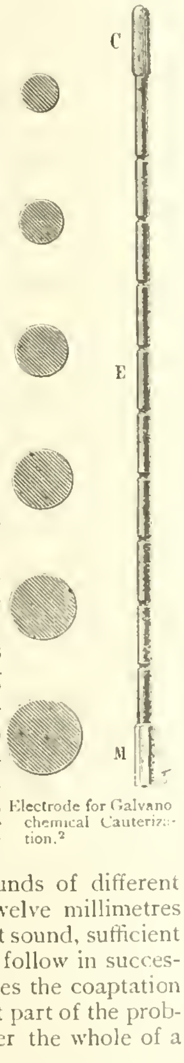
Such was my ordinary practice till lately, when a few instances of failure led me to try the effect of the positive puncture on some patients, in whom the reaction from the negative punctures had caused too great inconvenience or alarm, and on others whose hysterical temperament made the negative punctures insupportable. First I tried with steel needles, but I was thwarted in two ways. First, they oxidized and became immediately useless; and then the oxidation, together with the dry eschar formed around the electrode, created an obstacle, which no one as yet had noted, to the passage of the current, and consequently caused a diminution of the electrical supply. Thus, other things being equal, while a negative galvano-puncture furnished an intensity of one hundred and fifty milliampères, that of the positive puncture did not exceed fifty milliampères. To free myself from this difficulty, I put aside the steel trocars and replaced them by a fine gold needle, which is not acted upon in the same way and will last for some time. The only precaution to be used with this needle is, that it must not be allowed to remain in contact with any mercurial solution, which disintegrates metals, and renders the gold brittle. The vaginal irrigations must, therefore, be made with the carbolic, or other antiseptic mixtures, to the total exclusion of all mercurial preparations. I may say that I have great confidence in these positive punctures for fibroids, especially when we encounter persistent pains; and I even have recourse to them when the pain seems to be connected with a state of peri-uterine inflammation.

II. HEMORRHAGE.—I believe that we may improve our way of treating hemorrhage, and render it shorter and more decisive. We occasionally fail for two reasons: 1st. That all the bleeding membrane inside the uterus is not equally and uniformly cauterized; and, 2d. That we have not used a current strong enough to cauterize sufficiently.

1st. *Irregular cauterization.* — I employ a straight platinum sound, which answers perfectly well in a small uterus with a small cavity. But its action lessens in proportion as the extent of the mucous membrane enlarges. This may be owing either to the instrument moving too freely and coming in contact with only one surface of a large cavity, or to some inequalities of surface such as are found in the hour-glass form of uterus, when the small straight sound touches only isolated points, cauterizing some to the utmost, while others escape altogether. I overcome these difficulties in two ways :

a. After a multiplicity of experiments I have devised a new electrode, which is soft, and not only a good conductor, but harmless and quite aseptic. It is composed of gelosine[1] and can be made to mould itself upon the whole of the uterine interior. It must be previously sterilized either by open boiling and then cooling, or by exposing it in the containing vessel to a temperature of from one hundred to one hundred and twenty degrees centigrade. This matter is then introduced into the cavity of the uterus, so as to fill it, by means of a long piston-like sound of some insulating material, such as hardened caoutchouc or celluloid. The metallic stem of this piston-sound may then be used as electrode, and the current, passing through it, to the centre of the gelosine paste, thence radiates over the whole mucous membrane. There is another way of making use of this gelosine packing. Withdraw the piston-sound when the cavity is completely filled, and plunge a metallic sound, insulated nearly up to the point, into the middle of the gelosine, and make connection with the battery.

b. I succeed in cauterizing the whole of an irregular cavity by progressively increasing the size of the electrodes, so that in the end the entire surface is brought into contact with the conducting body. To do this with sounds of gold or platinum, the only available metals, was a costly affair, and I instructed Gaiffe to make for me a series of seven sounds of gas-carbon,[2] which conducts readily, is little subject to the action of the positive pole, and may be had cheap. I possess therefore a case of seven sounds of different sizes, rising from five millimetres to twelve millimetres in diameter. Beginning with the smallest sound, sufficient dilatation may be made for the others to follow in succession, till it is found that one of them gives the coaptation required. This is the solution of the first part of the problem—the equal spread of a current over the whole of a large or irregular uterine cavity.



Electrode for Galvano chemical Cauterization.[2]

2d. *The uterine mucous membrane insufficiently cauterized.*—The coagulating or hæmostatic action—local and polar—which we seek at the positive pole, under ordinary circumstances, will be strong and efficacious according to the quantity of acid disengaged ; that is, in other words, it will vary in proportion to the electrical intensity. Now, there are two means by which we can regulate the intensity, at the points of entry and discharge of the current.

a. The first is to engage a large number of elements. We may thus apply in certain cases an intensity of current varying from one hundred to three hundred milliampères. But with regard to these degrees of intensity, we must not lose sight of two considerations, the safety of the uterus, and the tolerance of the patient. If a few women are able to bear unflinchingly, without chloroform, as much as two hundred or two hundred and fifty milliampères, there are many more in whom it is impossible to make the dose exceed one hundred or one hundred and fifty milliampères. Now in a uterus of large size, where it would be necessary to introduce an electrode of proportionate length, perhaps fifteen or twenty centimetres long, this latter strength of current would not answer our purpose. For it is with electricity as it is with other natural forces, that power diminishes as the surface is extended. We see this in a water-course, where the mechanical effects of a confined portion of the stream are reduced to insignificance if the bed be much widened.

b. This leads to the adoption of the second and more practical means of attaining the same end. We vary and augment the intensity at the points of contact of the poles without altering in any measure the total interpolar intensity. The surface of the active electrode must be diminished or its density increased. It is understood that, with a greater intensity in an electric circuit, the action of the two poles will be different according to their respective size. Here, then, in varying the extent of the electric surface, we have the means, at will, of rendering the poles active or indifferent. It is easy to make this accommodation in regard to the uterus. We wish to produce a vigorous cauterization, without increasing the general interpolar intensity beyond the point easily supported. Lessen the intra-uterine electrode by one-third, or fourth, or a fifth of its original length, and forthwith the cauterization or topical action at the seat of contact will be made, thus, four or five times more powerful. I therefore lay it down as a rule in severe hemorrhagic cases, where it is expedient that a patient should bear a high dose of electricity without much suffering, that the intra-uterine electrode be reduced to a very trifling length ; though, under such circumstances, it is essential that it be passed from one extremity of the cavity to the other, so that every part of the mucous surface is successively and completely cauterized. I began my operations in 1882 with a metallic sound, bare only at the extremity. In my first essays in cauterizing the mucous membrane of the uterus I had no other. Now I have improved the instrument, and my electrodes of carbon, though of different sizes, are all of the same length, two and a half centimetres. The metallic stem of this instrument is covered with caoutchouc, and on it, at distances of two and a half centimetres, lengths which correspond with that of the carbon electrode, I have slight circular grooves marked. The electrodes are applied as follows :

1st. After disinfection in some strong antiseptic solution, in order to secure full cauterization the instrument is driven as far as it will go ; if possible, to the end of the uterine cavity.

2d. When the electrode is in this position, the highest bearable intensity of current is turned on, and we judge of the necessity of augmenting by the effect of previous operations. The intensity must be increased when the electrodes of larger volume, and consequently of more surface, are taken into use.

3d. The first stage of cauterization being finished, the instrument is withdrawn just as much as the length of the carbon, and in that situation the second cauterization is effected the same as the first, and so on, changing the position of the carbon till all the interior of the uterus is cauterized section by section. To do this methodically, the index-finger is passed into the vagina, and the pulp and nail pressed on to one of the circular grooves of the stem. While, in shifting the seat of action, the other hand retires the sound, the index-finger in the vagina remains immovable, and gives information as to the extent of change of position of the electrode by the touch of the following mark.

---

[1] *Gelosine:* Gelosine is the mucilaginous principle recently extracted by M. R. Guerin, chemist, of Paris, from the gelose of the *Gelidium corneum*, a sea-weed of Japan, found in abundance at Singapore.

[2] Electrode for Galvano-chemical Cauterization, one-third of actual size. C, Gas-carbon, two and a half centimetres long, rounded at the extremity. It is fastened by a screw to the end of the metallic stem. It may be replaced by others of the same length, but of different sizes. The diameters, gradually increasing from five to twelve millimetres, are represented by the shaded circles. E, Circular grooves, at regular distances of two and a half centimetres, on the caoutchouc covering of the metallic stem of the electrode. M, Handle of the electrode to which the rheophore is attached.

4th. It is better, if possible, to cauterize the entire cavity at one sitting, letting each sectional cauterization last from three to five minutes, as the gravity of the case and the size of the cavity may show to be proper.

5th. In continuing the treatment, the duration and force of the current must be made to depend upon the effect produced by the cauterizations at previous sittings.

6th. It is well to be aware that, when the cauterization of the neck of the uterus is once made, the electrode, in passing through the internal orifice for further action, will occasion much more pain. I believe I was the first to mention the fact that the neck of the uterus, which is so little painfully affected by ordinary caustics, the hot iron, or the knife, is, on the contrary, very sensitive, and much more so than the body, to the electrical currents, either induced or continued.

I think, in conclusion, I may say that it will henceforth be admitted we have in electricity a most powerful means of safely treating fibroid tumors, and that it will in future be felt as a duty by the surgeon to make use of it before adopting other measures. Carrying out my method as I have directed, I am convinced it will yield to others the same new and interesting results that it has been my good fortune to witness.

5 RUE MOLIÈRE.

THE USE OF LARGE DOSES OF CALOMEL IN PNEUMONIA.

By JAMES McMANUS, M.D.,

BROOKLYN, N. Y.

LOOMIS, in "Pepper's System of Medicine," states: "The mortality-average (in pneumonia) from all the published reports to which I have had excess gives 20.1 per cent. of deaths."[1] Everyone knows that pneumonia is a very fatal disease; and it is further known that the mortality-rate varies greatly. Some observers give the rate as low as two per cent., and others place it as high as thirty to thirty-five per cent. Thus Bennett[2] lost but four cases out of one hundred and twenty-nine; while Loomis[3] lost thirty-four per cent. of two hundred and fifty-five cases treated in the wards of Bellevue Hospital. Wilson Fox[4] says: "In fifty-five cases from the case books of University College Hospital and the North Staffordshire Infirmary I have met but eight deaths, but in all of these the attending circumstances were such as fully account for the mortality." Loomis states:[5] "Between the ages of forty and sixty the death-rate is from ten to twenty-five per cent.; uncomplicated cases will recover." And yet on the same page he admits having twelve deaths in a total of one hundred and thirty-one uncomplicated cases.

From all of these varying statements it appears a hard matter to judge of the exact mortality of pneumonia; and in estimating the value of any special line of treatment the death-rate alone cannot be relied on. In January, 1885, I was called upon to attend a man who was just entering upon the second stage of pneumonia. He had been sick for two days. The night before I was called in he had taken ten grains of calomel. I found him with a temperature of 99½° F., a pulse of 88, and respirations 20 to the minute. He had pneumonia on the right side involving the entire lung. The respirations afterward increased to 28, pulse to 112, and as the end approached went considerably higher, but the temperature never rose above 100° F. Dr. A. J. Rooney saw the case in consultation with me and confirmed the diagnosis. In spite of large doses of carbonate of ammonia, digitalis, and nux vomica, and liberal stimulation, he died on the sixth day of the disease.

The day after his death I read an editorial in THE MEDICAL RECORD (January 24, 1885) entitled "The American Treatment of Acute Croupous Pneumonia," which spoke in rather enthusiastic terms of the use of large doses of calomel in the treatment of pneumonia. After reading the article I could not help feeling that my patient's chances for recovery would have been much better if he had taken thirty to forty grains of colomel instead of ten, and I determined to try the calomel treatment on the first opportunity. Within the next week I was called to two cases of acute croupous pneumonia, both women and mothers of families, aged from thirty to forty. I put both of them on the calomel treatment and each recovered promptly, with an average sickness of about seven days.

CASE I.—Mrs. B——, thirty-two years of age, of Irish parentage, mother of one child, ten months old, had a pneumonia of right lung involving the lower and middle lobes. She had had a severe chill, followed by pain in side, slightly rusty sputa, temperature of 103° F.; pulse, 108; respirations, 36. The patient was just entering fully into the first stage of pneumonia when I was called. I immediately ordered thirty grains of calomel, and then gave her carbonate of ammonia, five grains every two hours. In the morning I found all her symptoms very much improved: Temperature, 100° F.; pulse, 80; respirations, 24. The bronchial breathing was not very pronounced, and slight subcrepitant râles began to appear. The evening of the third day the temperature, pulse, and respiration increased slightly, temperature running up to 101° F., pulse to 88, respiration to 28. The exhibition of the calomel had been followed by only one large so-called bilious stool. On the evening of the third day I gave twenty grains more of calomel. The next afternoon she had a severe sweating, followed by all the subjective and objective symptoms of a resolving pneumonia. She was completely convalescent in ten days.

CASE II. was very similar to Case I. Patient had severe pain in side; temperature, 104° F.; respirations, 40; pulse, 112. Had been taken sick twelve hours before I was sent for. I found dulness at the base of right lung, with bronchophony and bronchial breathing; while a little higher up some crepitant râles were to be heard. I immediately ordered thirty grains of calomel and a mixture containing quinine and ammon. carb. in syrup of tolu and mucilage of acacia, giving a dose of the first two of five grains each. The next morning—about fourteen hours later—I was surprised to find my patient very much better; temperature, 100° F.; pulse, 80; respiration, 20! the pain in the side completely gone, and the signs of the third stage of pneumonia setting in. She had had one natural stool. The next day the husband of the patient called to tell me that his wife was so much better that I did not need to call. I afterward heard that she was out two days after, or on the fifth day of the sickness.

The next case was that of a man—a veteran of the war—of about forty-five years of age. He had been three days sick when I was called, during which time he had been treated by a homœopath. He had pneumonia involving the lower lobe of left lung completely, which was just beginning to involve the upper lobe. His temperature was 104½° F.; pulse, 112; respirations, 44. I gave him forty grains of calomel and five grains of ammon. carb. and two and one-half grains of quinine every three hours.

In six hours his temperature was down to 102° F., pulse reduced to 96, and respirations to 38. The next morning (twenty-four hours after), the temperature had fallen to 101° F., pulse to 88, and respirations to 28. The evening of the fifth day the temperature again went up to 102½° F., the pulse to 100, and respirations to 34, but twenty grains of calomel brought them all down again; on the seventh day crisis set in, and he went on to a slow but uninterrupted convalescence though he was not completely restored to working strength for six weeks.

[5] Pepper's System of Medicine, vol. iii., p. 343.

Since then I have had fifty-nine cases of true croupous pneumonia, at all ages and of both sexes, have treated them all with calomel, and all have recovered promptly, with the exception of four which I shall proceed to describe.

One was a man, suffering from syphilis and chronic alcoholism, who suddenly developed a pneumonia of the right side. He immediately went into the wild maniacal delirium which is familiar in chronic alcoholics with pneumonia. He died on the fifth day of his sickness, but rather, I think, from œdema of the brain than from the pneumonia, for it seemed to me, from the imperfect examination of his lungs which I was able to get before he died, that the pneumonia had begun to clear up. In addition to his other troubles he had a chronic diffuse nephritis, so that it seems to me hardly fair to class his disease as pneumonia *per se*. Dr. James Watt saw the case in consultation with me, and agreed to all of the above.

A second one of the four was a man whom I was called upon to treat on the eighth day of his sickness. He was about thirty-six, and had been treated by a good physician up to that time; but on the morning of the eighth day the man's friends and the doctor had some dispute, and the doctor refused to attend him any longer, so I assumed charge of the case. He died in the crisis the next day, about sixteen hours after I was first called. I gave him only twenty grains of calomel.

The third case was that of a young man, a hard drinker, aged about twenty-eight years. He was treated by someone else for three days before I was called upon. The doctor who attended him believed that he was developing intermittent fever and did not examine his lungs. The diagnosis of pneumonia was confirmed by Dr. Edmister and by Dr. G. R. White.

I gave him forty grains of calomel and had the satisfaction of seeing his temperature fall from 104° F. to 101½° F.; his respirations from 48 to 32; and his pulse from 116 to 90 within twelve hours; but, at the end of the second day after, his temperature went up again to 103° F., and the pulse and respirations became correspondingly increased. More of the lung became involved, and he continued under my care, still suffering greatly, for about three months, when his trouble ran into chronic pneumonia or a fibroid phthisis, from which he is yet suffering, though I was first called to him in May, 1887.

The fourth case which did not recover promptly was a man about forty-nine years of age—a hard and steady drinker—but who had reformed about four months before his pneumonia developed. Calomel was given to him and it had its usual effects on pulse, temperature, and respiration; but it was fully three months before he completely recovered, and then not till he had a change to mountain air.

The success I have had with these sixty-two cases, but, more than all, the effect of calomel on pulse, temperature, and respiration; and the fact that in no recent publication—to my knowledge at least—is the calomel treatment spoken of, leads me to lay my experience before the profession

[illegible] staying the ravages of the disease. I do not believe that such unsatisfactory results will ever follow the course of treatment indicated and outlined above; nor do I believe that tertiary syphilis will ever develop in a single case thus treated.

Mrs. —— came to me two years ago with syphilis fully developed in its secondary stage. Her vulva had been ulcerated and tender for a month, and upon the labiæ were clearly developed chancres. Her person was covered with the eruption, and her mouth contained mucous patches. Her husband had been from home for a year and returned, three months previous to her visiting me, with a "sore" upon his penis. Without knowing its nature he inoculated her. I ordered euonymin with iodide and stillingia, and after continuing these for three months the lesions disappeared. Upon her own responsibility she then discontinued treatment, and there has not since been seen a single development of the disease.

Mr. ——, called upon me three years ago with a perfect Hunterian chancre upon the foreskin of the penis. Without waiting for further developments I placed him upon the alterative pills with iodide and stillingia. The only secondaries that appeared were a few papules upon the forehead and scalp, with alopecia. In three months these had disappeared. He continued the treatment one year, with several intermissions from a week to a month at a time, and he gained [illegible] and his gen-

I give from thirty to sixty grains of calomel not later than the third day of the disease. A smaller dose may be again given later.

Its effects are: It reduces pulse, temperature, and respiration, diminishes the pain, and renders the further progress of the case more comfortable to the patient, and, I firmly believe, brings on the crisis earlier. From such large doses of calomel you will rarely get more than one or two loose, though otherwise natural, stools.

445 Eighth Avenue.

IS A PROLONGED MERCURIAL COURSE ADVISABLE IN SYPHILIS?

By J. S. PRETTYMAN, Jr., M.D.,

MILFORD, DEL.

The medical profession, having ceased to question the propriety of a prolonged mercurial course in syphilis, is engaged in ascertaining new methods of administration, for the failures of the past must not be attributed to anything less than the faulty introduction of the remedy into the system. Fumigation, inunction, and alimentary introduction have proven alike discouraging, and now is offered the promised healing through hypodermic medication. To doubt the efficacy of the treatment is heresy; for it is the remedy of the fathers, the remedy *par excellence* of the children's children, the one specific in the disease!

For decades, and even centuries, from generation to generation, in treating syphilis the profession has been taught to depend upon mercury, and notwithstanding the results have proven unsatisfactory, and in many cases disastrous, it has declined to abandon the treatment, or even to investigate other remedies.

That a protracted course of mercury is not devoid of danger none can gainsay, and while we may administer it boldly, even heroically, it is with secret misgivings as to its results. "It is probable that as much injury has been inflicted by the use of mercury in primary syphilis as good has been accomplished by its administration in the constitutional forms of the disease. And when it is considered that every simple sore following a suspected coition was apt to be treated as syphilitic, by mercurialization of the system, it may be a question whether, on the whole, the medicine has not been more mischievous than useful. In regard even to true chancres, although mercurials will sometimes hasten their cure by lessening their induration, and may thereby postpone constitutional infection, it does not in any case prevent that result. In certain states of the primary sore mercury aggravates the disease" (Stillé). Whatever beneficial effect it may have in controlling syphilis is due solely to its alterative properties, and while there are less dangerous drugs combining these qualities and exerting as great an influence over the disease, we are certainly not justified in wholly rejecting these and continually resorting to mercury. Much injury, no doubt, has resulted from the injudicious use of the many salts of this metal, and as there are better forms of treatment, it is full time that the profession should halt in such recklessness; and be brought to consider the demerits of the old methods in connection with the merits of the new.

Admitting all that the most sanguine advocate can claim for the old method of treatment, it is only after months and years of continuous administration that we can hope hand retires the sound, the index-finger in the vagina remains immovable, and gives information as to the extent of change of position of the electrode by the touch of the following mark.

4th. It is better, if possible, to cauterize the entire cavity at one sitting, letting each sectional cauterization last from three to five minutes, as the gravity of the case and the size of the cavity may show to be proper.

5th. In continuing the treatment, the duration and force of the current must be made to depend upon the effect produced by the cauterizations at previous sittings.

6th. It is well to be aware that, when the cauterization

[illegible] that it is without power in this stage [illegible],

and we are thus forced into the position of either acknowledging the inefficiency of a mercurial course, and that the metal has not the specific qualities hitherto assigned it by the profession, or else that the so-called "tertiary syphilis" is not syphilis at all, but some other form of disease.

"Tertiary syphilis," with its putrid flesh and rotten bones, syphilographers claim is non-infectious. With the system thus completely saturated with the poison, every corpuscle laden and bearing it on its way, why should the *tertiary* be non-infectious while the primary and secondary stages are so virulent? Has the disease changed? Its nature has; and does it bring a doubt into our minds as to whether it is syphilis or not? May it not, after all, be the result of a prolonged mercurial course of treatment? for such are the very lesions we find in chronic mercurial poisoning. I quote from the "National Dispensatory" as follows, and how strikingly it confirms the above assertion:

"Among the constitutional effects of mercury are cutaneous eruptions, generally in the form of eczema, sometimes in that of febrile rubeoloid eruption, and more rarely as an eruption of bloody bullæ. Deep, foul, and intractable ulcers sometimes occur; they are most common within the cavity of the mouth and throat, and may prove fatal by hemorrhage or by exhaustion, the ulcerative process sometimes destroying the cheeks and the soft parts of the throat. It appears probable that mercury may give rise to periosteal nodes which sometimes advance to the destruction of the bones. The muscles lose their firmness and waste, the complexion turns pallid and earthy, the gums grow spongy, the hair falls out, the bones and joints suffer dull pains," etc. Isn't this an exact description of so-called "tertiary syphilis?"

Listen also to what H. C. Wood says in his work upon therapeutics; and he is a strong advocate for the mercurial treatment: "The persistent medicinal use of mercury has resulted in the production of a state of the system characterized by great anæmia, emaciation, and general loss of power, with loss of the hair, aching pains in the bones and joints, œdema, fetid breath, diarrhœa, and general disordered secretions; . . . the emaciation, the perverted functions of nerves and glandular tissue, the various skin-eruptions, the altered blood of chronic hydrargyria, all point to a profound impression, affecting the nutrition of every part of the organism."

I have repeatedly heard an intelligent, experienced physician, who has been in practice forty years, declare that he had never seen a case of syphilis advance to the tertiary stage which he had treated from the initial sore, and that he had never prescribed a grain of mercury in the disease. My own experience is in accord with this, and under the vegetable alteratives with iodides I have yet to meet with the first case that has developed beyond secondaries, and these are usually very light.

It is singular that after the disappearance of secondary lesions the disease should remain quiescent for years and then reappear in its most dangerous form. It is not reasonable to suppose that the virus, or microbe, would remain in the system so long a time inactive, and without the slightest manifestations of its presence, suddenly to renew its destructive work.

Consider, in connection with this, the fact of the slow elimination of mercury from the economy, and we have another reason for attributing the lesions to the action of the metal. Mercury has been recovered from the tissues eight weeks after administration, and it is believed by physiologists and therapeutists that it will remain in the system for years.

The magical power of the iodides in tertiary syphilis is appreciated by all, and when we consider that they materially aid nature in the elimination of mercury, we have strong negative evidence confirming the conclusion that "tertiary syphilis" is not syphilis at all, but chronic mercurial poisoning, and that the wonderful effect of the iodides is thus due to their power in assisting the economy to rid itself of the cause.

Administer iodides after a mercurial course, and ptyalism follows. Under other circumstances they do not salivate, and this result may either be attributed to their forming with the metal very soluble salts which are rapidly eliminated through the mucous membranes, or else to their action upon the glandular system, stimulating and aiding in depurating the system. So well, indeed, is this understood that the "mixed treatment" has come into vogue, and many practitioners regularly follow the mercurials with iodides.

If so-called "tertiary syphilis" results from the administration of mercury, it may properly be asked why this development does not occur in all cases where the metal is thus given? For the same reason, we reply, that a few grains of the mild chloride does not always produce ptyalism; for the same reason that a few drops of the liquor sodii arseniatis does not always cause œdema! In many cases nature successfully resists the intrusion, while in others the vital forces are overcome, and the metal remains permanently, to soften and destroy.

In treating syphilis the iodides alone are unreliable, just as mercury is; but in combination with irisin, phytolaccin, euonymin, leptandrin, podophyllin, etc., the results are most gratifying. As comparatively little harm can follow this treatment, it is well to begin the remedies early in the disease, without even waiting for secondary appearances, for we may thus shield many of our patients from the mortification of public exposure.

After the symptoms have sufficiently developed to render the diagnosis secure, I prescribe somewhat as follows:

℞. Potas. iodide.......................... ℥ ss.
Syr. stilling. comp....................... f. ℥ vj.
M.
S.—Dessertspoonful three times a day, half an hour before each meal, in a wineglass of cold water. Also,

℞. Podophyllin............................ gr. x.
Irisin,
Phytolaccin.............................āā ℈j.
M. et ft. pil. xl.
S.—One at 10 A.M., and one at 3 and 9 P.M.

To these may be added sodæ bicarb. ℈j.–℈ij.; it seems to render the resins less irritating and more assimilable. The liver and entire glandular system is thus kept actively at work, and the poison is rapidly eliminated, much of it passing out with the ejecta from the alimentary canal. With an occasional intermission of the pills for a day or two at a time, when the catharsis is excessive, I continue the above course for several weeks, and I have never, in a single case, been disappointed in its effects. In place of the pills I frequently substitute euonymin.

had been treated by a homœ- [illegible] preparation when

involving the lower lobe of left lung completely, which was just beginning to involve the upper lobe. His temperature was 104½° F.; pulse, 112; respirations, 44. I gave him forty grains of calomel and five grains of ammon. carb. and two and one-half grains of quinine every three hours.

In six hours his temperature was down to 102° F., pulse reduced to 96, and respirations to 38. The next morning (twenty-four hours after), the temperature had fallen to 101° F., pulse to 88, and respirations to 28. The evening of the fifth day the temperature again went up to 102½° F., the pulse to 100, and respirations to 34, but twenty grains of calomel brought them all down again; on the seventh day crisis set in, and he went on to mercurial, and it will promptly check the ravages of the disease. It will rarely be necessary to treat a case beyond six months, and the lesions will usually disappear in much shorter time. I append the history of a few cases to show the efficacy of this treatment:

I first examined Mr. —— in September, 1887. His mouth and fauces were covered with mucous patches, such as are generally seen in syphilis about the second or third month. No other lesions were apparent. He acknowledged having been infected, and stated that it occurred two years before. Since then he had been under the care of a distinguished specialist, and he was at that time taking mercury, and had been during the entire two years with but a few short interruptions. A copy of every prescription was shown to me, verifying the statement. I placed him upon the iodide and stillingia compound, as indicated above, with a teaspoonful of the elix. of euonymin between meals and at bedtime. In less than a week the ulcers had disappeared, but the treatment was continued a month. Since this there has been no return of the disease, and he has been under no other treatment.

Four years ago I treated Mr. ——. He was unmarried and twenty-eight years of age. Alopecia was decided, and a syphilitic eruption covered his entire person. His throat was in a dreadful condition, and it was with the greatest difficulty that he could even swallow liquids. This was one of the worst cases I have ever seen, and he had been continuously for four months under the mercurial treatment. In spite of this the disease steadily advanced, and he became discouraged and disheartened. I used the chlorate of potash solution as a gargle, and placed him upon the alterative pills with iodide and stillingia. In ten days his throat had healed, and he was taking solid food without difficulty; in thirty days the eruption had decidedly faded, and in two months was entirely gone. At the end of the fourth month he protested that he was well and wished to abandon treatment. I insisted upon his continuing it, and he did so for another month, when, upon his own responsibility, he ceased to take the medicine. He was engaged and anxious to be married. I explained to him the dangers of such a step, and insisted upon a postponement of the wedding. Through the importunity of the lady he consented to the union, and much to my surprise, and contrary to my advice, in two weeks they were married. In a year and a half their first child was born, and he is now a robust, healthy boy, and has never manifested the slightest indications of the disease. A second child has since been born to them, and this also is healthy and free from the trouble. The father has received no further treatment, nor has the disease reappeared upon him. The mother has never aborted nor shown the slightest sign of having been infected.

Failure is recorded in these cases for the mercurial treatment, and success for the vegetable alteratives with iodides. Two years was more than ample time, under proper treatment, to have wrought a cure, but in the first case mercury proved inadequate, as it has done in thousands of cases before. In the second case the remedy was given continuously, and in large doses, for four months, and it had apparently no beneficial influence in overcoming or in staying the ravages of the disease. I do not believe that such unsatisfactory results will ever follow the course of treatment indicated and outlined above; nor do I believe that tertiary syphilis will ever develop in a single case thus treated.

Mrs. —— came to me two years ago with syphilis fully developed in its secondary stage. Her vulva had been ulcerated and tender for a month, and upon the labiæ were clearly developed chancres. Her person was covered with the eruption, and her mouth contained mucous patches. Her husband had been from home for a year and returned, three months previous to her visiting me, with a "sore" upon his penis. Without knowing its nature he inoculated her. I ordered euonymin with iodide and stillingia, and after continuing these for three months the lesions disappeared. Upon her own responsibility she then discontinued treatment, and there has not since been seen a single development of the disease.

Mr. ——, called upon me three years ago with a perfect Hunterian chancre upon the foreskin of the penis. Without waiting for further developments I placed him upon the alterative pills with iodide and stillingia. The only secondaries that appeared were a few papules upon the forehead and scalp, with alopecia. In three months these had disappeared. He continued the treatment one year, with several intermissions from a week to a month at a time, and he gained flesh and strength, and his general health was decidedly benefited. There has not since been the slightest manifestation of the trouble.

I am now treating a case of syphilis, and have been for three months, in which the disease has been kept so thoroughly under control that not even the immediate family of the patient has ever suspected the cause of the trouble. He has had a few mucous patches in his mouth, with half a dozen papules upon the scalp, and these have at present disappeared, and I do not anticipate a recurrence of the symptoms.

I have also relieved some of the worst cases of psoriasis and chronic eczema with the above treatment in from four to six weeks. In connection with these remedies, I usually prescribe as a local measure the application of a solution of ammonium muriate, its strength depending inversely upon the amount of irritation produced. If this course of treatment is faithfully carried out it will give far better results than the arsenical, or any other that I have ever tried or have any knowledge of. From the fact of the cure following the administration of the iodides, many will assert that the diagnosis was incorrectly made, and that the eruption was but the cutaneous manifestations of syphilis. But this is all nonsense, for I have verified the results too frequently to be deceived. I recall a case of chronic rheumatism which I treated several years ago with potas. iodide. The prescription accidentally came into the hands of a fellow-practitioner, who informed the man that I was treating him for syphilis! I was vigorously denounced by the patient, but he afterward repented and followed out the treatment, and was rewarded by a cure.

MICROBES IN THE SKIN, AND SUPPURATION.—Dr. V. A. Kryloff, who has been investigating, in Professor Ivanovski's anatomical and pathological laboratory in St. Petersburg, the causes of acute suppurative processes, has obtained some interesting results by rubbing antimonial ointment and croton-oil liniment into shaved patches of the skins of different animals. When these substances were rubbed into the skin of guinea-pigs and rabbits, no pustules, as a rule, were produced; but by means of very energetic rubbing a dry gangrene of the skin was caused, in which no micro-organisms were to be found—a condition apparently due to an absence of pyogenic organisms in the skin of these animals. In one case, however, there was a pustulation, and staphylococcus aureus was found. When a similar experiment was tried on dogs, pustulation always followed, and staphylococcus pyogeneus albus was invariably found; this coccus existing, as it would seem, in the skin of the dog, otherwise it would be difficult to explain why other staphylococci were not found. Cultures were also prepared from the normal skin of dogs which, injected into other animals, produced abscesses, and in the case of rabbits proved rapidly fatal. The conclusion that Dr. Kryloff comes to is that the production of pustulation by external irritants depends, in part at least, on the preexistence of pyogenic organisms in the skin. In the case of dogs, he thinks that they must be localized in the deeper layers of the epidermis, as thorough disinfection was a very difficult proceeding; and unless the organisms lying deeply were destroyed, their power of provoking suppuration was not arrested.—*The Lancet*, June 9, 1888.

A PATHOLOGICAL CONDITION OF THE MIDDLE TURBINATED BONE.

By JONATHAN WRIGHT, M.D.,

BROOKLYN, N. Y.

The subject of nasal stenosis has received lately the attention of many laryngologists, and has been the theme of many valuable papers.

The increase of our surgical armamentarium, and the recognition of the condition as a cause of many reflex and direct respiratory and neuralgic phenomena, have given to the subject an interest and an impetus which promise to result in valuable additions to our knowledge of nasal and laryngeal disease.

In 1882, Dr. Bryson Delavan[1] pointed out the fact that true hypertrophy of the turbinated bones, especially of the middle, is a frequent occurrence in connection with deviations of the septum. Zuckerkandl,[2] in the same year, in a work which has become classical, points to the same condition. That deviations of the septum often exist in connection with this hypertrophy cannot be denied after such extensive researches, but it is equally certain to the clinical observer that the hypertrophy exists without any marked deviation of the septum in a great many cases.

Baumgarten[3] and others believe that the turbinated bones, when hypertrophied, are the chief causes of deviation of the septum.

Bresgen[4] declares, and a very short consideration of the subject must convince anyone, that an acute coryza could never in itself, however frequently it might occur, cause a deviation of the septum by a simple swelling of the mucous membrane covering the turbinated bones. Indeed, I doubt very much whether a chronic hypertrophic condition of the mucous membrane can be a *cause*, unless the bony structure itself is stiffened by pathological changes, thus forming a point of support, which the normal bone *cannot*. That a bony hypertrophy can cause a deviation is undoubted.

Beside the researches of Zuckerkandl and Delavan, Bayer[5] and Glassmacher[6] mention bony cysts, and Knapp[7] and Sprengel[8] speak of osteomata which were observed to have indented and pushed over the bony septum from its normal position.

It is not, however, the aim of this article to discuss the causes of deviation of the septum, however much they may be connected with bony hypertrophy of the intranasal structure, but rather to consider the causes, symptoms, and treatment of the pressure exerted by the middle turbinated bone upon the septum, whether due to a true bony hypertrophy or a displacement of the bone from its natural position upward and inward.

We see a great many cases in which the mucous membranes of the septum and of the turbinated bones are in contact, and without a doubt many nasal passages present such an appearance, and do not, as a rule, give rise to subjective symptoms. When, however, there is firm bony pressure, I believe it is always pathological, and sooner or later it will give rise to symptoms more or less severe, and to sequelæ more or less serious.

The normal turbinated bone acts as a delicate framework over which are stretched periosteum, stroma, bloodvessels, nerves, submucous and mucous tissue. The middle turbinated bone and the opposing surface of the septum, with the regions above, are the seat of the olfactory sense.

The variations in its size and form are very great. While Zuckerkandl gives its average length as ten to twelve millimetres on its anterior free border, he says: "The length of the middle turbinated bone undergoes many variations in different persons. I have in my possession preparations with smooth middle turbinated bones, which in their anterior measurements are thirty millimetres broad, while the nasal passages have only a length of forty-one millimetres; consequently the smelling cleft (Geruchspath), and the area over which the branches of the olfactory nerve spread are a great deal larger than in normal cases. An inequality in the size of the middle turbinated bones is not infrequent, and I have observed that *one* may be ten millimetres shorter and lower than its companion. However, other conditions are the causes of this, as deviations of the septum, tumors, etc."

That bony union occasionally takes place between the turbinated bones and the septum as the result of disease, is certain, but these cases are not to be included among those under consideration. The normal turbinated bones being spongy in their structure, and the periosteum being supplied with elastic fibres, are resilient and spring readily into place after being depressed by a probe. Posteriorly, they can be seen in the rhinoscopic mirror standing out as hoods from their attachments. When expiratory efforts are made by blowing through the nose, the inferior turbinated bones being under the lee of the soft palate, do not feel the full force of the air rushing up from below; but not so with the middle turbinated; they, from their position and form, must receive the expiratory blast and rise with it, shutting it out from the regions above to a great extent. The olfactory region being above the lower free border of the middle turbinated, is the reason why foul smells from pharyngeal ulcerations, dead bones, etc., or from fermentations in disordered conditions of the stomach, are not perceived by the sufferer, but made very apparent to his companions. The sense of taste having been proved to largely depend on the olfactory sense, a certain amount of air must necessarily ascend from the pharynx, but that it must take place in a comparatively quiescent condition of the pharyngeal air, a smoker can easily prove to himself, by first sniffing the smoke of a fragrant cigar as it arises from the lighted end, and then drawing it into the pharyngeal space and expelling it through the nasal passages by an expiratory effort. If the elasticity of the middle turbinated bone is normal, the difference in the intensity of the fragrance will be very marked. Anteriorly, the inspired air to a great extent passes almost vertically past the free ends of the inferior, and a certain amount above that of the middle turbinated bones, while posteriorly, the hooded ends direct the expired air out through the middle and inferior meatus. The secretions from the mucous membrane lining the various nasal cavities, and the sinuses connected with them, flow down over the turbinated bones, keeping them moist and evaporating in the inspired air, and dripping when excessive from the nostrils in front, or from the uvula to the base of the tongue behind.

As for the histological changes in the cases under consideration, I have little to say, inasmuch as it is a condition resulting from various pre-existing morbid conditions, and not a disease in itself. There is usually atrophy of the mucous membrane, although it may be hypertrophied. The bones themselves have usually undergone what I presume to be condensing osteitis,[1] though I have not been able to find anything directly bearing on the subject in medical literature. Often it is associated with nasal polypus and polypoid degeneration Occasionally one may observe the condition which Dr. Woakes, from very unwarranted grounds, it seems to me, is pleased to call necrosing ethmoiditis,[2] the name itself, if nothing more, being a misnomer.

I have never seen it before the age of sixteen, having most frequently observed it from thirty to fifty, though I have several cases now beyond that age. Following the

[2] Nasal Polypus.

rule of all chronic nasal catarrhs, it is much more common in women than men. While agreeing perfectly with Dr. Delavan as to the predisposing causes of the bony hypertrophy, something more must be added to explain the close apposition of the bone to the septum, as in many, if not most, cases the free border of the bone is displaced upward and inward.

The manner of its production I believe to be usually, though not always, as follows: The patient has been a sufferer from chronic hypertrophic rhinitis, which may or may not have gone on to an atrophic stage. The structures of the turbinated bones and their envelopes, undergoing the changes due to their catarrh, lose gradually their natural resiliency. Now, when the patient, already a sufferer from chronic hypertrophic rhinitis, has a fresh exacerbation—a coryza, as they so constantly do—or even when they are not so suffering, but feel the stopping up of the nasal passages from the exaggerated action of the so-called erectile tissue, violent expiratory efforts are made to force the air through and clear the passages of obstruction and of mucus. The air rushing up from below strikes against the hords of the middle turbinated bones, swells them out like sails, and forces them upward and inward against the septum. This is constantly repeated until the damaged organs become permanently fixed in their new position, the bones undergoing changes in the meanwhile by which their further movements are rendered impossible. The turbinated bone and the septum are equally unyielding. Union may now take place between the mucous membranes, but most frequently does not unless there has been ulceration, or the bones and the opposing septum have been wounded by attempts to pass probes, snare, wire, etc., between their surfaces. This is the condition of the middle turbinated bones in these cases when they present themselves for treatment. It is often marked by accompanying lesions, polypi, hypertrophy of the mucous membrane, or the graver condition of ethmoidal suppuration. Many cases, however, present nothing but this abnormal position of the bones and an atrophic condition of the mucous membrane. The contact may exist the whole length of the border of the bone, or only over a portion of it—in the latter case usually posteriorly.

As so often happens the patient may for years have had a chronic rhinitis, producing the well-known atrophic or hypertrophic changes, without having had his attention drawn to his nose by the slight symptoms. On cross-examination we often find that, for a longer or shorter period antedating, patient has noticed at times stopping of the nasal passages, that he has suffered very frequently from coryza, but has not thought much of it. The nasal cavities are so small that the range of symptoms caused by the various forms of pressure is limited. Hence it is that subjective symptoms are of comparatively little value in differentiating their causes. They may be of all degrees of severity, and may be aggravated or masked by coexisting or dependent lesions. The most common and distressing symptom is pain, which may be confined to the bridge or one side of the nose, or may be supra-orbital, or may be referred to the vertex or occiput, and is often a general headache. This pain may be constant and subject to severe exacerbations, but more commonly is more or less intermittent, a coryza always very greatly increasing the pain.

Harrison Allen,[1] in an excellent article on catarrhal headaches, very clearly defines and differentiates this form, and a further consideration would be but a repetition of his work on my part. Other conditions,[2] as said above, may cause the same symptoms.

Scheck says[3] that he has found supra- and infra-orbital and infra-maxillary neuralgias, or migraine, rare in cases of polypus, but frequent in cases of hypertrophy of the middle turbinated bones. Elsewhere[1] the same author speaks of bony cysts as causing by pressure anosmia, trigeminus neuralgia, and other neuroses, and compression of the tear-duct. I have seen one case of simple hypertrophy of the middle turbinated bone causing the latter condition, which was relieved by operation. Scheck's case of chronic spasm of the soft palate[2] was probably due to the same cause.

The reason of pain being such a prominent feature in these cases is that the mucous membrane of the nasal passages, and especially of the septum, is a very sensitive tract. If one wishes to form a slight idea of the pain induced by this condition, let a probe be passed between the middle turbinated bone and the septum, a little above the former, and a moderate pressure exerted upon the septum. If we add to this the exaggerated sensibility caused by coryza, we may have a fair idea of the sufferings of these, by no means rare, victims. I have seen a few cases in which the excessive flow of watery secretions[3] from the nose could only be accounted for by a very slight contact of the middle turbinated bone, which exerted an elastic pressure. By correcting this relief was immediately obtained, although several other means had been tried without success in one case. From the distribution of the olfactory nerve we should expect, and practically we often do observe, decided diminution in the sense of smell. Eye symptoms, conjunctival congestion, and lachrymation, are often noticed.

When we enter upon the field of reflex neurosis we stand upon very uncertain ground. It seems to me that we must wait for the physiologist to teach us more about the sympathetic system of nerves before we can build up theories on any sound basis. What we can say in nasal diseases is, that such and such pathological conditions are occasionally accompanied by such and such remote or near nervous phenomena, and that occasionally, by curing the nasal disease, we obtain an abatement of the so-called reflex symptoms. The error of first love, etc., is a very old one, but a very common one.

Burnton[4] speaks of the influence of the contact of the hypertrophic mucous membrane of the turbinated bones with the septum in producing reflex symptoms, which, he states, suddenly subside if the contact is prevented.

Hack[5] dwells especially on sneezing in connection with various inflammatory conditions of the middle turbinated bones and adjacent portions of the septum. He speaks also of other reflexes in the same connection. His well-known contributions to the subject, "Reflex Neuroses,"[6] may be referred to by those interested in that part of the subject.

A great deal of work has been done by others[7] in this field, but the subject so far has been approached principally from the clinical side, and very little is settled. How uncertain the conclusions are that are drawn is illustrated by the remark of Scheck,[8] that he has found some cases in whom treatment was directed to the evident seat of the neurosis, were cured, some were benefited, while some received no benefit at all.

A mention of two cases will serve to illustrate the forms of reflex disturbance I have noted in connection with bony pressure on the septum, and I do not doubt that other forms exist.

One of the patients was a young woman, aged twenty, who presented herself in a pitiable state of nervous and physical exhaustion after a siege of severe and long-con-

tinued sneezing, the paroxysms lasting sometimes for many minutes and often recurring a half-dozen times a day, extending over the period of ten days or a fortnight. Otherwise she was an exceptionally healthy patient, with no hysterical tendencies, and above the average intelligence. Since childhood she had been subject to attacks of sneezing, especially on catching cold, but they had only of late attained such severity as to incapacitate her for work or to confine her to the house. On examination, the left middle turbinated bone was seen to be against the septum, but not pressing at all firmly. On the right side there was, low down, a large cartilaginous spur which prevented a higher view of the nasal cavity. With a Bosworth saw I removed this ; I could then see that the right middle turbinated bone was pressing firmly upon the septum. I awaited the result of the operation on the septum, which was most gratifying for the time. So much so that, after trying with a probe and with a snare to relieve the turbinated pressure, I desisted from further efforts. For two or three months the patient was almost wholly clear of her distressing symptoms, though she still complained of headaches. Gradually, however, the paroxysms of sneezing returned, not in their former intensity, but gradually increasing. By two operations with the electric nasal trephine, I bored through the right middle turbinated bone in two places, removing pieces of very hard, stiff bone from the middle and posterior extremities. This gave her another respite from suffering, especially from the headaches. She has now, in the last few days, presented herself again with a history of a return of the sneezing in a modified form. I propose now to attempt a freeing of the bone throughout its whole extent, and I think with fair chances of complete relief from the most distressing part of the symptoms.

Another case which I have also still under treatment, may illustrate the asthmatic reflex, though the result has not been as encouraging.

A woman, about fifty-five years of age, had been treated for nasal polypi in the left nostril, having suffered for many years from asthmatic attacks when catching cold. She had also ethmoidal suppuration. After clearing away all the polypi in the middle fossa, the left middle turbinated bone was seen, much enlarged, covered with atrophic mucous membrane, and immovably fixed, indenting the septum by its pressure. There was not the slightest improvement from the removal of the polypi, and but slight from a partial removal of the bony pressure, though the headaches and the suppurative process have been benefited. From the age of the patient and the fact that emphysema is present, I cannot hope for much relief by the removal of the suspected origin of this reflex respiratory symptom.[1]

In a case uncomplicated by any of the forms of obstructive trouble, an anterior rhinoscopic examination reveals the middle turbinated bone covered by atrophic mucous membrane, and pressed so firmly against the septum that it is impossible to pass a probe, however thin, between them. A posterior rhinoscopic examination shows the space between the inferior and middle turbines much increased, and the latter high up and against the bony septum, the mucous membrane being pale and atrophic as in front. There is not necessarily any obstruction to the passage of air, as the respiratory region of the nasal passages lies below the middle turbinated bone. Ethmoid suppuration, while very apt to follow a complete damming up of the secretions, is not present in the majority of these cases, as drainage may take place anteriorly or posteriorly ; or the line of contact may be interrupted. Atrophy of the mucous membrane of the septum is occasionally observed below the line of contact, due probably to the pressure on the afferent blood-vessels. In addition to ethmoidal suppuration, we may have as complicating conditions general atrophic or hypertrophic rhinitis, nasal polypi, post-nasal and Eustachian catarrh, adenoid vegetations in the pharyngeal vault, and deviations of the cartilaginous and bony septum. These conditions may be singly or collectively present, and must have their appropriate treatment either before or after the procedures resorted to for relieving the pressure of the turbinated bone on the septum.

I think it probable that the condition may occasionally undergo a spontaneous cure, either by atrophy of the offending bone, or the symptoms may cease from the accommodation of the nerves, both sympathetic and sensitive, to the long and continuous pressure upon them.

It is much more likely, however, to continue indefinitely to cause suffering, or to be the cause of ethmoid and anterior suppuration, by completely damming up the excessive secretions which form on every coryza. It is very difficult to formulate any rule as to what cases should and what cases should not be subjected to operative treatment. The common sense and honesty of the physician must be depended upon for the answer.

When we come to the question of treatment, I wish to confess that I have not yet been able to devise any method by which every case may be successfully treated. Before anything is done, cocaine should be thoroughly applied, so that its maximum constringing power may be exerted. One is then able to see just how much of the apparent pressure is due to hyperæmia. If a flat, smooth probe can be passed with moderate force between the opposing surfaces, benefit can be expected from treatment of the catarrhal condition of the mucous membrane. Where there is a hypertrophic condition of the mucous membrane, alkaline and astringent sprays and douches often yield very good results. The galvano-cautery carefully applied, so that opposing surfaces of septum and turbinated body are not touched at the same time, will occasionally do all that is necessary ; though even with the greatest care adhesions are apt to ensue, when matters are worse instead of better. In atrophic conditions of the mucous membrane, of course, topical applications are of no avail. Nothing is to be gained, but pain is increased, by attempts to stimulate the atrophic membranes to action. Thudichum[1] speaks of using the galvano-cautery to burn his way up to the cribrous plate, but he does not say whether or not he destroyed bone in this way ; but in another connection lauds the cautery both for soft and bony growths. Burning away a hardened and hypertrophic middle turbinated bone is not a method which will recommend itself to the average operator, though the soft tissue can be reduced in this way without danger of too much reaction. Dr. Allen has in a similar condition made use of the finger, introduced into the nasal passages, to force and even break the bone away from its position.[2] Although I have no experience in this method, it seems to me the cases must be exceedingly rare where the average index-finger could be introduced high enough up, and far enough back, to accomplish the desired purpose. When one finds that an attack must be made upon the bone itself, one has a number of instruments from which to choose, and the one selected will be largely the result of individual preference and skill in its use.

I have never succeeded in breaking the bone with a stiff probe, as one made strong enough to do the work cannot be forced between the septum and the bone. Occasionally, the straight or curved scissors devised by Dr. Charles H. Knight, may be of service, but usually only in connection with other means. Several times I have made use of the nasal snare ; occasionally, by means of a probe notched at the end, the snare may be forced between the septum and the bone, and the latter included in the loop. When it has been effectual in removing the bone, I have always had cause to regret the use of the snare. One is almost sure to destroy the whole middle turbinated bone. This result cannot be too strongly deprecated. Greville MacDonald[1] condemns this procedure, so freely resorted to by Dr. Woakes and by Thudichum. It is a mutilation which should only be chosen as the lesser of two evils. Extensive suppurative inflammation of the ethmoid cells, or frontal or maxillary sinuses may require it, in order to remove an obstruction to free drainage and thorough and vigorous applications to the diseased points. A patient who has lost this important structure will be subject to complete or partial anosmia on the affected side, to catarrhal inflammations which may become atrophic, if not already in that condition, and to headaches and pain referred to the bridge of the nose. The operation of the snare, however slowly and carefully it may be done, when the whole bone is removed, may be followed by severe and prolonged hemorrhage, requiring the firmest tamponading with styptic cotton. I have no experience with the galvano-cautery wire in these cases, but it would be extremely difficult in its adjustment, and, minus the hemorrhage, open to the same objections as the cold snare. The instrument for which I have the greatest preference is the nasal trephine operated by the electro-motor. This is an instrument familiar at least to most laryngologists in this country, and described by Curtis,[2] Jarvis,[3] and Seiler.[4] I have used the "Challenge" motor and the battery known as the C. and C. The C. and C. motor is more powerful, but not so convenient and noiseless. Now, with this instrument (nasal trephine), if one were able to apply it in a straight line from one end of the offending bone to the other, the operation would be exceedingly simple; but as a matter of fact, one has to introduce the straight instrument from below and work, at least anteriorly, with the crown of the trephine pointed directly at the cribriform plate of the ethmoid, and often not knowing exactly how far that exceedingly delicate and important roof of the nasal cavities and floor of the anterior cerebral fossa lies above the middle turbinated bone. The latter is in such close relation to the septum, that the height of this roof cannot be ascertained by a probe. Reference to plates and skulls will only show the operator how much the distance varies in the normal skull. Moreover, one must bear in mind that the bone in these cases *is* nearly always higher than normal. The only guide that I have been able to use for gauging a safe distance is measuring on the outside from the margin of the nasal ala below to the inner canthus of the eye above. As the cribriform plate articulates a little above this point with the frontal bone, it is a tolerably safe, if not always an accurate, guide. I have never yet had an accident happen from introducing the trephine too far, but it is always with a feeling of reluctance that I push the instrument in this direction. Cocaine should be thoroughly applied to the seat of the intended operation. It is best done by means of pledgets of absorbent cotton soaked in a twenty per cent. solution. An excess of cocaine in the cotton should be carefully guarded against, lest several drops may trickle downward and backward into the pharynx and larynx, giving rise to hawking and gagging. This may be largely avoided also by causing the patient to bow his head upon the chest, so that the excess may run out anteriorly. When thus carefully applied the anæsthesia is complete, the operation comparatively painless, and constitutional cocaine effects entirely avoided.

---

[1] Since this article was written the patient has presented herself very much improved, and freer from asthmatic attacks than she has been for a long time. The flow of pus from the ethmoidal region is much less. Of course she has employed cleansing solutions and kept the nasal passages free of discharge by sprays and douches.

[1] Lancet, August 27, 1887.

[2] Internat. Journ. Med. Sciences, April, 1886, and Proceedings Am. Laryng. Ass., 1887.

First, then, an opening is made through the bone anteriorly, and a second, and perhaps a third one in line, posterior to the first. Then the operator is able to direct the point of the instrument more obliquely and in a posterior direction, thus working more in a line parallel to the line of contact. The operation usually requires two or three sittings, as after the first perforation blood is almost always sure to obstruct the field of operation, and it is safer and better to wait a few days, or even a week, until a clear view can be had. One should avoid as much as possible touching the septum with the cutting edge, but make the perforation just within the edge of the bone, leaving a margin of the bone or periosteum between the perforation and the septum. When the turbinated bone has been sufficiently weakened by this honeycombing process, with forceps, probe, scissors, or snare, the line of contact can be broken and the pressure relieved. The after-treatment requires fully as much attention as the operation itself. The nasal fossæ should be kept clean by carbolized alkaline douches, detached fragments of bone and mucous membrane removed, great vigilance being necessary lest adhesions form. This breaking of the bony framework without a complete destruction of the turbinated structure, while, of course, more difficult of attainment, and less effective in relieving the pressure, I think should always be attempted. The degree of success will depend largely upon the operator, but quite as much also upon the faithfulness of the patient in submitting to repeated manipulations. For, unless advantage is taken of the destruction of the bone, the line of contact broken up, and the bone forced away from the septum by firm tamponading with cotton, or by repeatedly forcing the bone outward, or by cutting away with scissors or snare the infringing portions, the track of the trephine will soon be filled up with a new formation of fibrous, cartilaginous, or possibly of bony, tissue.

I have never found it necessary to put these patients to bed after the operation, although, for a day or two, they may be confined to the house. I have never seen any considerable hemorrhage, though occasionally, for a day or two after the operation, there may be a moderate bloody discharge, which yields readily to astringents or to the pressure of the cotton tampon. Although I have had more satisfactory results from this mode of procedure than from any other, I am well aware how faulty it is, and am ready to abandon it for a better. It is very easy to meet the indications on paper with advising the removal of the obstruction, but I am sure that those who try it in practice will appreciate more explicit advice than is at present to be found in the articles on nasal obstructions. No doubt an external incision along the side of the nose, releasing the ala from the cheek and affording a larger opening through which to work, would greatly simplify matters, but the objections to this are obvious. Even when the operator has not succeeded in removing the bone from its contact with the septum, surprisingly good results are obtained in breaking up the firm bony framework and relieving the unyielding pressure, so that he should not too hastily decide upon the removal of the whole turbinated bone.

CINERARIA MARITIMA IN CATARACT.—The director of the Kew Botanical Gardens reports the following case in the *Pharmaceutical Journal* of May 26, 1888: A physician of Venezuela, who was suffering from cataract and had been operated upon unsuccessfully by an oculist in London, was induced by his relatives to try local applications of the juice of Cineraria maritima, a popular remedy in that country for this disease. Although without faith in the remedy, he yielded to the entreaties of his friends and began the instillation of two drops into each eye three times a day. He was totally blind at the beginning of this treatment, but at the end of four days had a faint perception of light, and at the end of two months could recognize people and could even tell the time with the eye which had not been operated upon. With the other eye he was able to count fingers held before it. The application caused only a temporary burning and increased lachrymation. The physician who was the subject of the alleged cure has not yet, however, come forward to confirm this remarkable statement.

Progress of Medical Science.

Intra-muscular Injection of Mercury in Syphilis.—The inconveniences to which mercury administered by the mouth is apt to give rise, and the uncertainty which exists as to the precise amount that is being absorbed, have led certain practitioners to resort to injection into the tissues, as a more reliable and, withal, a more convenient method of exhibiting the drug. The earlier attempts in this direction were not attended with the success that had been anticipated, inasmuch as they gave rise to so much pain and such untoward sequelæ as to render continuous treatment impossible. Since others, however, undeterred by the suffering in which they were not called upon to participate, carried their investigations further, it was found to be possible to administer the drug in this way without the untoward results which attended its employment in the first instance. In a paper read before the Medical Society of London, Mr. Astley Bloxam gave the results of a very extensive experience with the different preparations that have been suggested. The preparation which, in his hands, has proved the most uniformly successful and free from inconvenience, is a solution of *sal Alembroth*, containing perchloride of mercury and chloride of ammonium, ten drops of which is equal to a third of a grain of the perchloride. This he injects deeply into the muscles of the buttock. The proceeding is said not to be very painful, though as to this the opinion of some of the patients would be desirable, and no abscess has ever been known to follow. Its advantages are, that the stomach is not deranged, that one injection a week is sufficient to keep the patient under the influence of the drug, and that the disease may be cured with some seven or eight grains of the salt, spread out over a year or eighteen months.—*The Medical Press.*

Adhatoda Vasica.—Adhatoda vasica is a plant belonging to the natural order Acanthaceæ. According to Mr. Hooper the leaves have an expectorant and antispasmodic action, and are employed in consumption, coughs, chronic bronchitis, asthma, and other pulmonary and catarrhal affections. It is usually administered with some spice, as ginger or pepper. In Bengal the leaves are smoked as a remedy for asthma, and several European and native physicians have given evidence of some very satisfactory results. A well-defined alkaloid appears to be the most important constituent; it is the bitter principle and active part of the plant. It is soluble in water with an alkaline reaction; ether dissolves it, but less readily than alcohol. Hooper calls it "vasicine." Strong infusions of the vasica leaves added to pond water destroy animalcules. A solution of the sulphate of vasicine was added to some water in a basin containing a live frog, which soon died, as also did leeches. Flies, fleas, mosquitoes, centipedes, and other insects were also destroyed, so that the reputed use of the leaves in destroying injurious weeds in submerged fields appears to be founded on scientific principles. The infusion containing the alkaloid acts upon the vegetable cells in the same manner as certain chemical reagents, by causing shrinkage of their contents and then disintegration.—*The Lancet.*

Dextrocardia.—A case of right-sided position of the heart was recently shown to the Vienna Gesellschaft der Aerzte, by Dr. Gruss. The patient, a young woman, aged twenty, was badly developed, and complained much of dyspnœa and giddiness. There had been some improvement of late years. The pulsations of the heart on the right side of the sternum were noted at birth, and there had always been some cyanosis and feeling of coldness. There was no cardiac dulness on the left side; on the right it began at the fourth rib, extending inward to the right sternal border, and downward, being lost in the liver dulness. Auscultation revealed in the second left intercostal space a distinct systolic murmur, and there was a loud diastolic sound. The murmur was heard in both carotids. The pulse was very small, but otherwise normal. The abdominal organs were normally situated. The diagnosis made was pure dextrocardia and congenital pulmonary stenosis, without malposition of the viscera in general. Von Bamberger concurred in the diagnosis, and remarked that Professor Schrötter had lately stated that no single case of pure dextrocardia had ever been proved, whereas all anatomists of great experience, for example, Rokitansky, Friedberg, Förster, etc., had mentioned such cases, and he himself had seen two. The murmur was due to congenital stenosis, for the acquired kind was extremely rare, though he and Dittrich had described such a case (due to a kick of a horse). The loud second sound excluded the aorta as its origin. He thought also that the great vessels were not transposed; the case had gone on too favorably for that supposition. Professor Kundrat said that the great vessels might be transposed, the position of the septum to some extent correcting the malposition.—*British Medical Journal.*

Phlegmasia Dolens and Œdema of Infants.—Dr. Dumas has recently written a paper on the "Probable Identity of the Œdema of New-born Children and Phlegmasia Alba Dolens." He concludes that this œdema is but one symptom of phlegmasia dolens developed in the course of the first few days after birth (*British Medical Journal*). Its causes, though very varied, are essentially of the same nature as in the adult, and may be divided into predisposing and determining. The principal determining cause is the incomplete establishment of respiration, including pathological and other obstacles which that function may encounter before arriving at its perfect stage of efficiency. The symptoms of phlegmasia are the same in the new-born infant as in the adult, allowing for certain modifications in relation to the special physiology of the first days of life after birth. There is likewise the same pathological anatomy in both cases; but in the child the venous thrombosis is more often situated in the inferior vena cava. The treatment should be alike in both cases, and the same dangers are to be feared in the infant and in the adult, though the relative lesser vitality of the new-born child must always render the prognosis less favorable in its case than when its mother is similarly attacked. All the precautions by which impediments to the establishment of perfect respiration are overcome, including the avoidance of hasty and immediate ligature of the umbilical cord, together constitute the true prophylaxis against the affection in question.

Blood-pressure and Transudation.—Professor Lenaber has recently made a careful study of this subject. His conclusions may be set down as follows: All transudates, without exception, contain albumen in solution, but in less proportion than blood-plasma. The smallest amounts occur in the normal transudates, and in that of cutaneous œdema. The albumens are the same as those of the blood-plasma—viz., serum-albumen, globulin, and fibrinogen; but little is known as to the relative quantity of each of them. The amount of saline constituents is nearly the same as, and often in excess of, those of the blood. All transudates contain such non-colloid bodies as the blood happens to be holding in solution, bodies which never pass out in glandular secretion, such as biliary coloring matter and hæmoglobin. Substances which do not pre-exist in the blood are not met with in transudates, except as the result of decomposition, thus forming a distinction from glandular secretions. Filtration experiments outside the body are of no use in determining the influence of changes in blood-pressure upon transudation. The rise of venous pressure causes an increase in the quantity of transuded fluid and of its albuminous constituents, but does not appreciably influence the amount of its saline constituents. A rise in arterial pressure—*i.e.*, active congestion—appears occasionally to increase transudation; but there is no positive evidence of its producing any change in the amount of albumen transuded, or in that of the saline constituents.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, September 8, 1888.

THE RHYTHM OF MUSCULAR VIBRATION IN HEALTH AND DISEASE.

THE study of the phenomena of muscular contractions, and especially of those finer successive contractions forming normal and pathological tremor, has undergone some important modifications of late years. It used to be taught, and indeed still is taught in physiological text-books, that the ordinary muscular contraction is made up of a fusion of rhythmical contractions numbering about twenty a minute. With the stethoscope placed over a strongly contracted muscle, a musical note of a pitch corresponding to about forty vibrations per second is heard. This was taken to be an over-tone of a note whose vibrations numbered about nineteen per second. Telephonic examinations have apparently confirmed this view. Yet, on the whole there has been much doubt felt of late as to the exact number of physiological contractions going to make up an ordinary voluntary muscular contraction. Horsley and Schäfer have recently asserted, from experiments upon the stimulation of the central nervous apparatus, that the normal muscular rhythm is about ten per second. This is the rhythm found when the cerebral cortex, the white matter, or the spinal cord is stimulated. It may be assumed, therefore, at present, that the weight of evidence favors the view that the normal muscular rhythm is only ten per second.

Charcot has dwelt upon the diagnostic importance of studying the difference in the rapidity of the muscular movements in different forms of tremor. The tremors of slow rhythm are those of paralysis agitans and multiple sclerosis; those of rapid rhythm are: (1) alcoholic tremor, (2) mercurial tremor, (3) tremor of exophthalmic goitre. In the slow tremors the rate is four or five per second; in the rapid tremors it is eight or nine per second.

Drs. R. Norris Wolfenden and Dawson Williams have recently tried to show (*British Medical Journal*, May 19, 1888) that these distinctions must be accepted with some reservation. There is normally, they say, a fine vibration in the muscles of men voluntarily contracted, and the rate of this vibration is about ten per second. In pathological conditions the rate of this normal tremor is always preserved, but its amplitude is increased in various ways, and to a varying degree. In the so-called slow tremors of old age, paralysis agitans, and sclerosis, the apparent rate is five to six per second, but a careful study of properly registered curves shows that the apparent single vibrations are really made up of two, and that the slow tremor is therefore only one of normal rate in which every other vibration is imperfect. The rapid tremors they found to range at nearly ten per second. The conclusion is, therefore, that the special characteristics which clinically distinguish the various forms of tremor are to be traced to two causes: in the first place an exaggeration of the amplitude of the normal vibration; and in the second place to the fusion of vibrations, which has the effect of producing a relatively slow tremor, generally of a rate corresponding to half that of the normal vibration.

It is very probable that the normal muscular rhythm is not always exactly the same. It is well known that it varies greatly in different animals, and in different muscles (light and dark) in the same animal. Pathological variations, therefore, cannot be expected to occur in a very definite manner. As an illustration of this, Gowers found a variation in the tremor of paralysis agitans ranging from 4.8 to 7 complete oscillations per second.

THE LEPER SETTLEMENT ON THE ISLAND OF MOLOKAI.

IT is probably known to everyone that leprosy exists to a considerable extent in the Sandwich Islands, but few, except those specially interested in the subject, know to what an extent it exists there, or what are the measures in force to isolate the sick and prevent the spread of the disease. In the biennial report of the President of the Hawaiian Board of Health we find an account of the leper settlement by Mr. R. W. Meyer, agent of the Board of Health in Molokai, from which the following facts are taken.

The settlement is on the Island of Molokai, to which all lepers are sent as soon as their disease is recognized. On the first day of April, 1888, the number of lepers on the island was seven hundred and forty-nine, of whom four hundred and ninety-two were men and two hundred and fifty-seven women. It is curious to note that among this number were six British subjects, two Germans, one American, one Pole, one Belgian, and one Russian. Custom, and a bad custom it would seem, allows the relatives and friends of the sick to live in the settlement as long as they desire, and to leave it whenever they tire of their surroundings. Of these relatives and friends, called "kokuas," there were one hundred and forty-four. In addition to these there were forty-nine of the original inhabitants of the island or their descendants, called "kamaainas," who had not yet been driven away by their unwelcome neighbors. The entire population of Molokai, at the time of the report, was, therefore, nine hundred and forty-two. Of the buildings on the island, in addition to the cottages of the residents, there are twelve hospitals, two dispensaries, one house for the resident physician, one prison (with accommodations for two inmates), one receiving house for new-comers, one store, and five churches, of which two are Catholic, two Protestant, and, curiously enough, one Mormon. The total number of buildings is three hundred and seventy-four, of which two hundred and sixteen are owned by the sick or their friends.

The lepers, and the children born of leper parents at the settlement, are supplied with rations by the government, and also receive a bill annually which enables them to obtain at the store six dollars' worth of clothing, which is probably sufficient for the necessities of a warm climate. They are allowed to compound their rations for cash, if they so prefer. They also receive each half a bar of soap a month, and to every house or family is given one quart of kerosene oil per month.

There are certain defects in the management of the settlement, which, if leprosy is a contagious disease (and the weight of medical opinion is in favor of that view), are to be accounted very serious and call urgently for remedy. The most important of these is the fact that "kokuas," the friends and relatives of the sick, are allowed to reside on the island as long as they choose, and then to leave whenever they desire to return to their homes. In this way, assuming that the disease is contagious, they spread it about and render null all the efforts made to repress leprosy in the islands. Another reform that is called for is the removal of paid nurses and attendants, and the substitution for them of sisters and others who are ready to devote their lives to the care of the sick, with no thought nor desire of returning to the outside world after having amassed a comfortable sum by the accumulation of their salary. That the management of the lepers, as far as they are themselves concerned, is to be commended, is evidenced by a letter addressed to Father Damien by Dr. Woods, in which he says that, after having visited every one of those places where the disease prevails, he has not found the people so happy, so well taken care of and attended to as the Leper Settlement on the Island of Molokai.

News of the Week.

To Preserve Instruments from Rust.—The immersion of steel instruments for a few minutes in a saturated solution of potassium carbonate, is said to be an effectual preservative from rust.

An Entire Family Affected with Hydrophobia.—A Bohemian newspaper reports that all the members of a family living in Chrcitz, a small village in Bohemia, are suffering from hydrophobia. The father, a peasant aged fifty, was seized with symptoms simulating those of rabies. A physician was called, and while he was examining the man, who lay bound hand and foot on a bed, the daughter rushed upon him and tried to bite his hand. She was found to be suffering from the same affection as the father. Soon after the mother and her grown son were found in convulsions on the floor of an adjacent room, and finally, the maid-servant was seized with similar symptoms. Three physicians from the neighboring town of Kolin and one from Prague were summoned and pronounced the disease to be hydrophobia. At that time the father was already dead. The maid, who was least affected, said that the family had partaken, nine days before, of a goose which had been killed by a mad dog. This is the report as given in the *Deutsche Medicinal Zeitung*, which, however, does not vouch for the truth of the tale.

• Dr. Paul Langerhans, of Freiburg, has recently died in Funchal, Madeira, of pulmonary tuberculosis. He was aged forty.

Myxœdema in Albany.—In the July number of the *American Journal of the Medical Sciences*, Dr. Henry Hun, of Albany, reports four cases of myxœdema observed by him in that city. This is a rather remarkable showing for one city, as the author has been able to collect the reports of only one hundred and fifty cases in all in the medical literature.

The Perils of Medical Men in Russia.—The physician in Russia has not only to suffer from exposure to disease and from the malice of dissatisfied patients, but he sometimes also feels the reproving hand of his paternal government. Recently a Dr. Dreipolkher, an official connected with the hospitals of St. Petersburg, was requested to obtain admission to one of the hospitals for a sick woman. He sent her to several in turn, but they were all full and could not receive her, and she died in consequence of the exposure to cold. The government thereupon banished Dr. Dreipolkher to the Arctic regions of Archangel, probably with a view of making the punishment fit the crime, although the poor man had done his best to obtain shelter and medical care for the woman.

Gonorrhœal Rheumatism, according to Dr. J. B. Webb, attacks with especial frequency the temporo-maxillary articulations, a fact which he regards as one of considerable diagnostic value.

Loss of Life from Wild Animals and Snake-bites is said to have been unusually great during the past year in India. In 1887, no less than 1,203 persons so perished, the number for 1886 having been 1,109.

Iodoform Poisoning.—The absorption of iodoform gives rise to three distinct varieties of toxic symptoms, classified as the eruptive, the cerebral or delirious, and the syncopal forms. The eruptive form is the most common of the three. It is characterized by a reddish pimply eruption on various parts of the body, distant from the seat of absorption, and due probably to elimination of the poison by the cutaneous glands. In the cerebral form the patients may have epileptiform seizures or insomnia with delirium. The syncopal form is by far the most grave. Absorption is followed by a fall of temperature and algidity. In most cases the symptoms disappear on the discontinuance of the drug as a dressing, but it should in any event be employed with caution, as it is also liable to set up local irritation like any other powder. —*Medical Press and Circular*.

The Mother of Henry VII. of England (Margaret Beaufort, Countess of Richmond) was but a little past thirteen years of age when she gave birth to the future king.

Cheese Poisoning.—Many cases of cheese poisoning have been reported this season in Ohio. *The Sanitary Inspector* states that the State Board of Health of that State was, within a short time, notified of several cases, distributed as follows: At Urbana, sixty-five cases; Mansfield, fifty; West Liberty, thirty-five; Mutual, fourteen; Marion, fifty. The symptoms were vomiting, accompanied with much pain in the stomach, and, in many cases, violent purging. The sickness usually lasted from twelve to forty-eight hours, and great prostration was a marked feature, with syncope in some cases; no deaths occurred.

MEDICAL OFFICERS FOR THE STATE MILITIA.—The following official order has lately been issued by Adjutant-General Porter:

GENERAL HEAD-QUARTERS STATE OF NEW YORK.
ADJUTANT-GENERAL'S OFFICE,
ALBANY, August 28, 1888.

General Orders, No. 17.

I. Upon the recommendation of the Surgeon-General, persons appointed to medical offices will hereafter be examined, before being commissioned, by special boards selected by the Surgeon-General and hereby appointed:

For the First Brigade: Major Robert V. McKim, Surgeon 1st Brigade; Major Daniel M. Stimson, Surgeon 7th Regiment; Major Nelson H. Henry, Surgeon 12th Regiment.

For the Second Brigade: Major George R. Fowler, Surgeon 2d Brigade; Major John F. Valentine, Surgeon 32d Regiment; Major William E. Spencer, Surgeon 23d Regiment.

For the Third Brigade: Major Herman Bendell, Surgeon 3d Brigade; Major Lewis Balch, Surgeon 10th Battalion; 1st Lieutenant Daniel S. Burr, Assistant Surgeon 20th Separate Company.

For the Fourth Brigade: Major Roswell Park, Surgeon 4th Brigade; Major Charles G. Stockton, Surgeon 74th Regiment; Major Albert H. Briggs, Surgeon 65th Regiment.

Returns of appointments of medical officers will be referred by the commanding officers of brigades to the boards appointed for their respective commands, and all concerned will be governed by the rules prescribed in General Orders No. 14, series 1887, from this office, so far as the same are applicable.

II. Appointees to medical offices shall be further examined in the standard branches taught in legally incorporated medical schools; the diagnosis and treatment of injuries and diseases to which troops may be exposed; the means employed for the urgent relief, and for the transportation, of sick and wounded, including stretcher drill (see Provisional Manual of Instruction, U. S. A.); camp and personal hygiene; and as to their knowledge of official papers relating to their department.

III. It appearing that there are hospital stewards who are not qualified, according to the laws of the State, to perform the duties required of them, commanding officers are directed to discharge such from the service at once. Hospital stewards should have passed an examination before the State or County Boards of Pharmacy, and have received licenses as pharmacists.

By order of the Commander in Chief,

JOSEPH PORTER,
Major-General and Adjutant-General.

THE YELLOW FEVER.—From the time of the first appearance of yellow fever in Jacksonville up to September 5th, there had been three hundred and twenty-eight cases, with forty deaths. This is below the average mortality of the disease, so that the epidemic may be called a mild one. The authorities are making every endeavor to disinfect the city and to keep it clean, but nevertheless, new cases are constantly occurring, and it seems not improbable that the epidemic will continue as long as it has material to feed upon, or until cool weather comes. The action of Surgeon-General Hamilton, of the Marine Hospital Service, in restricting travel from the infected city, has been rather severely criticised, but we think not justly. The Government has not established a strict cordon sanitaire around the city, but has instituted a quarantine station at some distance from the infected region, where the refugees are detained for ten days. Some of the residents have also been transported by through trains directly to places in the North which are considered safe, and where no objection is raised to their reception. Fumigating stations have also been established for the disinfection of baggage. Among those who have died is Dr. W. L. Baldwin, a graduate of the Albany Medical College, who formerly practised medicine in Geneva and Utica, in this State, but who has resided in Jacksonville for the past nine years. A case of yellow fever has been discovered in Philadelphia, and a schooner with yellow fever aboard is detained at the Delaware Breakwater. The season is, however, so far advanced, that no fear of an outbreak of the disease in any northern city is felt.

HEREDITARY CHOREA.—There is a form of chorea occurring in adults, and even in advanced life, which has not been very clearly delineated. It is peculiar, inasmuch as the only appreciable cause is heredity. In every case one or other of the parents has been afflicted in a like manner, and it differs from the classical forms of chorea in the ability of the patient, by an effort of the will, to procure a temporary cessation of the disordered muscular movements. The malady is insidious in its onset and tedious in its course, and sooner or later the patient manifests symptoms of mental derangement, which causes his career to finish in an asylum. It generally occurs between forty and fifty years of age, and is not amenable to treatment. —*Medical Press and Circular.*

THE ITALIAN SOCIETY OF INTERNAL MEDICINE.—A new medical society has been established in Italy, modelled after the German society of the same name. The meetings are to be held annually in Rome, and the first one will be held in October next. Among the subjects to be discussed at this meeting are Fever and Antipyresis, Diabetes, the Treatment of Tuberculosis, Etiology and Treatment of Pneumonia, and Cardiac Gymnastics in the Treatment of Heart Disease. The Committee of Organization consists of Professors Baccelli, Cantani, Galassi, Maragliano, and Rossoni.

SIR MORELL MACKENZIE is writing his reply to the German doctors, or, as he prefers to call it, the history of the Emperor Frederick's illness. The book will be issued late in October or early in November.

DR. HENRY VAN ARSDALE died at his home in this city on August 25th. He was born in New Brunswick, N. J., in 1814. He was graduated at Rutgers College and at the University of Pennsylvania. About 1838 he began practising his profession in this city, and was actively engaged in it until ten years ago, when he was obliged to retire on account of ill health. Dr. Van Arsdale was one of the first members of the New York Academy of Medicine, and was a member of many other medical societies in this city and elsewhere. The immediate cause of his death was pneumonia. His wife and one son survive him.

American Dermatological Association. — Programme of the Twelfth Annual Meeting, to be held at Willard's Hotel, Washington, D. C., September 18, 19, and 20, 1888. Officers for 1888: President, Dr. I. E. Atkinson, of Baltimore, Md.; Vice-President, Dr. P. A. Morrow, of New York; Secretary and Treasurer, Dr. G. H. Tilden, of Boston, Mass.

First Day.—Tuesday, September 18. Business Meeting (with closed doors), at 9.30 A.M. Report of Council; Appointment of Nominating and Auditing Committees; Proposals for Active and Honorary Membership; Miscellaneous Business. Morning session, at 10.30 A.M. Papers: Address, by the President, Dr. I. E. Atkinson. 1. The Electrolytic Decomposition of Organic Tissues, Dr. G. H. Rohe. 2. The Value of Salicylic Acid in Dermatology, Dr. Heitzmann. 3. Hereditary Dermatoses, Dr. J. C. White. Adjournment at 1.30 P.M. Afternoon Session, at 3.30 P.M. Papers: 4. A Report of Four Cases of Dermatitis Herpetiformis, Dr. J. E. Graham. 5. Dermatitis Herpetiformis, with notes of three cases, Dr. H. W. Stelwagon. 6. Personal Observations on Skin Diseases in the Negro, Dr. R. B. Morison. 7. Note of a case of Filaria Medinensis, Dr. A. Van Harlingen. Adjournment at 5.30 P.M.

Second Day.—Wednesday, September 19th. Business Meeting (with closed doors), at 9.30 A.M. Reports of the Treasurer and Auditing Committee; Report of the Nominating Committee and Election of Officers; Election of Active and Honorary Members; Selection of Time and Place of Next Meeting; Miscellaneous Business. Morning session, at 10.30 A.M. Report of Committee on Statistics; Report of Committee on Nomenclature. Papers: 8. So-called Acne Anthracoide Iodopotassique, Dr. R. W. Taylor. 9. Note Relative to the Vegetative Lesions induced by Ingestion of Some of the Iodine Compounds, Dr. J. N. Hyde. 10. Notes on Some Unusual Cases of Skin Disease, Dr. W. A. Hardaway. 11. A Contribution to the Clinical History of Alopecia Areata, Dr. A. Van Harlingen. Adjournment at 1.30 P.M. Afternoon session at 3.30 P.M. Papers: 12. The Non-identity of Lichen Planus and Lichen Ruber, Dr. G. H. Fox. 13. The Question of Relationship between Lichen Ruber (Hebra) and Lichen Planus (Wilson), Dr. A. R. Robinson. 14. Multiple Pigmentary Sarcoma, Dr. E. B. Bronson. 15. Dermatitis Plantaris and Palmaris, Dr. L. Duncan Bulkley. Adjournment at 5.30 P.M.

Third Day.—Thursday, September 20th. Morning session at 10 A.M. Papers: 16. Raynaud's Disease and Symmetrical Gangrene in Late Syphilis, Dr. R. W. Taylor. 17. The Relations of Framboesia to Syphilis and Tuberculosis of the Skin, with Report of a Case, Dr. P. A. Morrow. 18. Kraurosis of the Vulva (Breisky), Dr. C. Heitzmann. 19. Molluscum Contagiosum, a Clinical Report, Dr. H. W. Stelwagon. Retirement of Old and Induction of Newly Elected Officers. Adjournment at 1 P.M.

A Remedy for Toothache.—Dr. Hofmann recommends the internal use of sodium salicylate, in doses of ten grains every half-hour, for the relief of toothache. As a rule, after two or three doses the pain is greatly diminished or ceases entirely for a time. When the ache is dependent upon caries, the relief obtained is but temporary, and the pain returns unless the cause be removed.

Another Impostor and Borrower is visiting physicians in this city. He introduces himself as a real-estate agent of Elizabeth, N. J., and a brother of a well-known physician of that city. The man is genteel-looking, his manner quiet and dignified, and he appears about dinner time with the story that he has suddenly found himself without enough to pay his fare home, having failed to find a friend who was to supply him. The sum he wishes to borrow, $1, is trifling in itself, but whoever lends it will gain so much by experience for the next man.

Transplantation of Skin from a Corpse.—Dr. Bartens reports, in the *Berliner Klinische Wochenschrift* of August 6, 1888, a case of successful skin transplantation. The patient was a boy, aged fourteen, who was suffering from a loss of the integument of both feet consequent upon a burn. Some skin was taken from the legs of a man, aged seventy-five, who had died twenty minutes before, and was transplanted to the boy's feet. Cicatrization of the ulcers promptly followed.

Rhus Poisoning is said to yield quickly to the local application of fluid extract of Grindelia robusta.

Dr. J. N. Freeman, of Brooklyn, N. Y., died of typhoid fever, August 18, 1888, while on a visit to some friends in Omaha, aged sixty-three years.

"The Annals of Gynæcology."—It has been asserted that a certain food company owned and controlled the *Annals of Gynæcology*. This the publishers of the journal deny. They state that the company in question made with them a liberal contract for advertising, but that the text of the journal is under the exclusive control of the editor, and that nothing in the nature of an advertising puff has ever appeared there.

The Exactions of Medical Study.—A correspondent writes to inquire if he could obtain a diploma in medicine without having to give up his business. He could certainly obtain no diploma that was worth the having unless he devoted at least three years to hard study, to the exclusion of other work. He does not mention what his business is, so we cannot say whether he would or not be obliged to give it up. But if it is a business that demands much of his time, he could not continue at it and study medicine, as it should be studied, at the same time.

One Advantage of being Color Blind.—Dr. M. G. Parker, writing in the *Annals of Gynæcology*, says that one who is color blind is able to focus an object in photo-micrography much better than one with normal vision.

Deaths in Battle.—The Red Cross Society has published some statistics concerning the German losses in the Franco-Prussian war. The total losses in killed and wounded during the war were 98,233, of which 0.7 per cent. was by the bayonet, 1.2 per cent. by the sword, and 98.1 per cent. by firearms. Of the latter 91.6 per cent. was from musketry fire, and 8.4 per cent. from artillery fire.

Methylal in Delirium Tremens.—Dr. Krafft-Ebing asserts that he has obtained excellent results in the treatment of delirium tremens by the use of hypodermic injections of methylal. He says that it is indicated in cerebral anæmia, but is unfit for cases of cerebral excitement due to hyperæmia of the brain.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

(Special Report for The Medical Record.)

Fifty-sixth Annual Meeting, held at Glasgow, Scotland, August 7, 8, 9, *and* 10, 1888.

Tuesday, August 7th—First Day.

Dr. J. T. Banks, the retiring President, occupied the chair and opened the meeting with a few remarks. He congratulated the Association on their meeting in Glasgow, now the second city of the empire, and assured them of a hospitable reception in the ancient university. The past year had been one of prosperity in the Association. One year ago, when he became President, the membership was 11,000, now it is 12,000. He congratulated the Association heartily on the selection of Professor W. T. Gairdner, of Glasgow, as President for the present year, and introduced that gentleman to the Association.

Professor Gairdner on taking the chair said that he would not boast on putting on his armor; it was not the time. It was the occasion, however, for Professor Banks to boast, for his work had been accomplished. Professor Gairdner said that though it was too early to boast, it was not too soon to be thankful for the honor conferred on him by the Association in electing him to the chair.

Dr. George Cameron, M.P., moved, "That the warm thanks of the Association be tendered Dr. Banks for the courteous manner in which he had presided during the past year, and that he be elected Vice-president for life.

Sir George H. B. Macleod seconded the motion, which was carried by acclamation.

Council reported new branches as follows: Perthshire, Nova Scotia, and Cape Town, South Africa. Two others in Tasmania and Malta are about to be formed. The number of members on the register last year was 11,107. During the year 359 resigned, 132 died, 1,649 new members were elected. Present number, 12,265. Income, £28,680; expenditures, £26,060 17*s.* 8*d.*; surplus, £2,619 2*s.* 4*d.*

Relative rank in the army came up in the Parliamentary Committee's report, and received much discussion. The report was adopted.

THE INEBRIATES LEGISLATIVE COMMITTEE

made a lengthy and encouraging report, which was adopted. They had changed the name of the act from Habitual Drunkards' Act to Inebriates' Act. Many declined to be called habitual drunkards, yet acknowledged themselves inebriates, and many were not habitual in their dissipation but periodic. The legislation is now permanent, in place of the temporary act for ten years which has just expired. In Great Britain, as well as in the United States and in the Colonies, the move toward this object has been originated among medical men.

Services were held in the old cathedral, which was crowded to its utmost with the doctors, who

SANG THE ONE HUNDREDTH PSALM

with a will, where King Edward, Oliver Cromwell, and many other noted ones had worshipped. The sermon, by Principal Caird, was a counterblast to modern materialism, and as forcible and cogent in argument as the language was beautiful and refined. He dwelt at some length on the arguments to be deduced from death and the loss of reason, and concluded by two objections absolutely fatal to the materialistic theory of the relation of matter to life. First, the theory was in irreconcilable opposition to the very law of the conservation of energy on which it professed to rest. Further, the fundamental objection to all material theories was that they begged the question at issue.

A resolution, stating it to be the opinion of the Association that Irish and Scotch diplomas should possess the same privileges as diplomas from other divisions of the United Kingdom, which was brought up at the Dublin meeting one year ago, passed unanimously.

THE PRESIDENT'S ADDRESS,

by Professor W. T. Gairdner, of Glasgow, was then listened to by the Association with great interest and profit. The President took for his subject

THE PHYSICIAN AS NATURALIST.

In no other language, he said, besides our own, has the title physician, or physicist, survived and threatened to engulf the term medicine—the art of healing. The physician is regarded as a student of nature. It is hard to find where this idea first took shape.

For a series of interminable ages, from the time, perhaps, of Hippocrates downward to what we call the dark or middle ages, the tradition has continually existed that the healer or physician of the highest class ought to be in every sense of the word a student of nature, a naturalist, or perhaps a man of science; and that he is trustworthy as a healer or physician chiefly in proportion to the confidence reposed in him as a naturalist—that is, an humble, reverential, and exact follower, or student, of nature. That magnificent opening of "Novum Organum" describes man as

THE MINISTER AND INTERPRETER OF NATURE.

He must be, according to Hippocrates, the servant of nature. Hippocrates was the first to observe nature and her works. This term, servant of nature, according to Galen, will only apply to the true healer, and not to the mere druggist, who might be called the enemy and adversary of nature and the sick.

The physician of the middle ages, so far as we can judge of him from literature, while retaining the name, was in a very small degree, if at all, cultivated according to the type. In fact, anything like original research was dangerous on his part, and liable to be punished by imprisonment, perhaps the fagot. I apprehend that the physician of the middle of the seventeenth century in France, unless caricatured out of all recognition by Molière, must have been altogether the most stupid, pompous, brainless formalist that ever in any age of the world practised the art under a learned title. Even down to the last century men of the type of Linacre and Cairns, in the Royal College of Physicians in London, greatly predominated over the

MEN OF SCIENCE AS EXEMPLIFIED BY WILLIAM HARVEY.

The physician *naturæ studiosus* was in danger of being wiped out; but the revival came, and now in the Scottish universities chemistry as a science, and perhaps botany, have never lost a distinctive place in the curriculum medical from that day to this. I wish I could say the same of physics proper—natural philosophy, as we call it—which has been, comparatively speaking, left out in the cold or treated as a step-child. In botany we have at least one opening into the science of observation, which though often depreciated by persons calling themselves practical men, has maintained its ground among us, and has had added to it more or less of zoölogy, of comparative anatomy, and natural history in general. During the hundred years past Scottish universities have been, with more or less success and amid considerable discouragement, laboring on the whole to build up again the great and noble idea of the physician as *naturæ studiosus*, a nature-seeker, naturförscher. It has been claimed that the spirit of modern science is ungenial and hard, even pitiless, and therefore not at all fitted for the ministrations of humanity; that it tends to make the suffering man a mere case, a thing to be observed and noted rather than a man of like passions with ourselves, and therefore to be treated with consideration and sympathy. There may be just a grain of truth in this; yet all the evils inflicted on suffering humanity by the physician as scientist have been but a drop in the bucket as compared with those which have sprung from the too lavish adoption of traditions in which there never was any trace of the scientific spirit at all.

When we consider that most of the great advances of the present day—stethoscope, microscope, laryngoscope, ophthalmoscope, sphygmograph, and electricity—involve applications of pure physics which are neither very remote from practice nor yet very easily mastered by the beginner, and that in the case of electricity and other physical reagents, even heat and cold, etc., we are every day extending the domain of these sciences in therapeutics, and still more perhaps in preventive medicine and sanitary science, their claim for an extended recognition in teaching seems to enormously enhance. I am persuaded that the physical laboratory will become an absolutely essential preliminary step in the education of the physician of the future, and that those who have not undergone this training will be hopelessly distanced in the race.

The want of early training in physics and the natural sciences next received attention. He lamented the unprepared state in which most boys and young men leaving school are as regards the most elementary truths of physical science and the observation of nature. Twelve or fifteen hours per week are devoted to classics, and

TWO OR THREE HOURS ARE CONSIDERED SUFFICIENT FOR SCIENCE

in most schools. This renders more than ordinary care necessary to insure, at the very beginning of the medical education, the preparation in physics which will shortly become all in all to the true physician.

No child is too young to take in the a b c of science—the manner how and the reason why, as Kingsley puts it. Children should not be taken from the age of six from learning of nature, and have their noses poked into books and papers for ten long years, till their eyes become myopic, and their brains suffer a corresponding deformity.

RELIGIO MEDICI

was next considered. *Ubi tres medicis, duo athei*, is a proverb the source of which it is impossible to trace, but which is evidently the growth of the mediæval period. This proverb is a calumny and a reproach. Yet to be accused of atheism in the middle ages might be the reverse of a real reproach to any men or set of men; to be tabooed with atheism has often been a compliment of the highest order.

The physician of the future, he believed, would be much more, instead of less, inclined to make his study of the Bible than hitherto. He will study it in the spirit of modern scientific freedom and historical research, and thus only, it seemed to the speaker, that the reconciliation of science and religion can ever be brought about.

On motion, a very hearty vote of thanks was unanimously passed for the scholarly manner in which the President had addressed them.

WEDNESDAY, AUGUST 8TH—SECOND DAY.

In the morning of the second day of the meeting of the Association, about a couple of hundred gentlemen assembled in the Queen's Rooms, Clifton Street, as guests of the Scottish Temperance League and the Scottish branch of the Medical Temperance Association, who hospitably entertained them by an excellent breakfast. The chair was occupied by Sir William Collins, formerly Lord Provost of Glasgow, and son of a very distinguished teetotaller well known in the temperance world.

SIR WILLIAM COLLINS, after warmly welcoming the visitors, pointed out that in numerous declarations, signed by some of the most distinguished medical men of the day, it had been admitted that

ALCOHOLIC BEVERAGES ARE THE FREQUENT CAUSE OF SEVERE DISEASES,

are not essential to healthy persons, and are sometimes productive of evil even when prescribed medicinally. He therefore thought that the time was approaching when the members of such a humane profession as that of medicine should attempt to aid the efforts of the total abstainers of the laity by themselves abandoning the use of alcohol, and thus influencing the world by their example as well as by precept.

DR. MCKENDRICK, Professor of Physiology in the University of Glasgow, said that the great majority of the medical men present were quite cognizant of all that could be said on the side of abstinence from alcohol; and the value of such banquets, he thought, was that they encouraged the isolated abstainers to resist temptation from without, since union gave force. He hoped that many who were present and were teetotallers would join the Medical Temperance Association. He knew in Scotland of many who practised abstinence, but did not like to join and pronounce themselves. These he urged to pass the Rubicon, and then they would assist others and be themselves encouraged! The day for arguments was almost passed. Action was now needed. The only plea of persons who clung to taking alcohol was for moderation; but what had convinced himself might perhaps prove of use to such waverers. He had said to himself when he took a little alcohol, "You take so little that it is hardly worth continuing to do so, and by giving up this small amount you may be of use to your weaker brethren." He then gave it up and became an avowed teetotaller. The total-abstinence cause was rapidly gaining ground among students, and many of them were total abstainers. These should meet together and encourage each other by discussions.

DR. ALFRED CARPENTER had some years ago addressed a Glasgow audience upon this topic, and had shown that one of the causes of drinking in Glasgow was that twenty-seven per cent. of the population of that city dwelt in one-room tenements. A whole host of diseases were due to the use of alcohol, as anyone could see who took up any casual newspaper and read the coroner's inquests. He warned medical men that if they gave up alcohol they must prepare for a struggle. Many of their patients might follow their advice, abandon alcohol, and then fall back into these habits, because they did not use enough fluids to take away the effete particles. Hence care must be taken to provide a substitute for alcoholic drinks.

At the opening of the afternoon session the President announced that there had been a letter received from the town of Leeds, requesting the honor of a visit from the Association in 1889. After reading this letter it was unanimously agreed that the invitation should be accepted, and that Mr. Wheelhouse, of that city, should be elected as President for the ensuing year.

MR. WHEELHOUSE thanked the Association for the honor it had done his city and himself, and, in the name of his fellow-citizens, promised to do his best to make their visit to his city as enjoyable as they could, and more than that, if possible a scientific success.

DR. CLIFFORD ALLBUTT then delivered an address upon the

CLASSIFICATION OF DISEASE.

It was an addition to a paper he had written on the same subject twenty-one years previously. He had long said to his students at Leeds that pathology contained nothing in it which might not be found in physiology; and insisted that comparative pathology was a word that as yet was scarcely heard. The profession of medicine ought to draw a very much greater amount of its knowledge of disease than it at present did from the study of the diseases of other animals. Nearly all remained yet to be done on this matter, although physicians had received considerable aid from the abler members of the veterinary profession. Disease must be studied in the smallest animals and in the embyro, if it were to be understood and appreciated in its simplest forms. Our present methods of investigation were, to use the words of Bacon, *mera palpatio.* Robert Houdin, the Parisian conjurer, used to mystify the Parisians by nightly illuminating only certain letters of the alphabet in turns, without any method, and something similar was the practice of pathologists in modern times. Modern medicine as yet had no principles, and neither had biology. The complicated nervous system of mammalia had been evolved from far simpler elements, and its diseases in their lower forms would have to be studied. It had been remarked that as civilization advanced the tendency of all human diseases had been to assume the neurotic type. But as the race was less civilized, so were the diseases it suffered from simpler and simpler. As the scale of animated life became simpler, the region approached where fever was impossible. There was no doubt that, in days gone by, the type of disease was much less complicated than it was at present, and that the change in the character of disease which had been explained away was a real thing after all.

When studying the subject of

HEREDITY,

in future, researches should embrace not merely the parentage, paternal and maternal of the patient, but should be far more wide-stretching, and the unity of disease should be kept in mind, since it would be necessary to interrogate as to what the diseases were which had carried off the various ascendants of the patients. The same inquiries must be made concerning the diseases of animals and plants. When a patient was strumous, asthmatic, or phthisical, it was important to ascertain what causes in his ascendants may have contributed to bring about this effect. All sorts of other diseases in the ascendants must be inquired into, since there was a tendency in disease of one kind to be transferred into another kind of sickness. Pathological races occasionally tended to appear and become a menace to the health of the community. It was a curious study to try to ascertain what diseases were caused by the environment, and what might be produced by long-continued custom. The inheritance of short prepuces by the Jews might be partly due to excision. Tabes dorsalis was often due to atavism, but might be caused by syphilis. Dr. Stephen Mackenzie had shown the connection of various skin diseases with other diseases in the parents. Under the name of gouty diathesis might perhaps be included the tendency to glycosuria and piles. It was thus obvious that the very best physical pedigree yet obtained was extremely imperfect. Then, again, the excretion of uric acid by certain persons reminded the comparative pathologist that some animals, such as birds, habitually excreted this substance, so that in this matter some human beings were kinds of birds. An able leader-writer in *The Lancet* had spoken of the connection between osteitis deformans and other affections of the bones, and observed that these diseases might be connected by looking into the history of the family in which they occurred. And so with regard to the diseases of the thyroid gland, it had been remarked that in the fœtus the tissues consisted chiefly of mucin. Thus in the case of myxœdema there was a retrogression of the tissues to the condition in which they were in the fœtus. Changes of function might gradually influence structures. Every vigorous race tended to expand and invade new territories. Hence less vigorous races were weeded out. Artificial selection of parentage might succeed in getting rid of diseased forms. Racial characteristics were very marked and lasting. Dr. Beddoes held that the diseases in the Welsh differed greatly from those of the English; and affirmed that cancer was more common in persons of dark hair than in those of lighter complexion. In Wales there was a more solid type of constitution. Dr. Beddoes asserted, also, that it was more difficult to rear fair-haired children in towns than it was to rear dark ones.

Sir William Roberts had alluded to certain curious types in diseases in the children of a Greek merchant residing in Manchester. The ancient Greeks were remarkable for the purity of their race, which was kept so by preventing the marriage of any but citizens. The Dutch were akin to the English in their types of disease. They tended to live a long time and to suffer from dilatation of the heart and from hemorrhage in the brain. The Scotch were rather inclined to despond. The South Briton accepted his illness well. The Celtic Irishman was voluble and cheery in the midst of disease. There was less nervous disease in Scotland, and scarcely any gout in that portion of the United Kingdom.

Dr. Billings had found that cancer was comparatively rare in negroes. The Irish and Germans in the United States seemed to be most affected by this disease. Hysteria was far commoner in France than in England. It was uncommon in Yorkshire. Negroes had an immunity from yellow fever, and a tendency to suffer but slightly from syphilis. But they had a proclivity to elephantiasis. The poison of beriberi would not attack Europeans, and attacked the Chinese far more frequently than it did the Japanese. It was remarkable that the Tzetze fly did not attack the buffaloes nor human beings, but was fatal only to domestic animals. Nor did it attack dogs fed on meat; but if the dogs were fed on milk they died from the bite. Dr. Bland Sutton had informed him that the quadrumana did not bear a low temperature, but that they did not become affected with phthisis. Rickets was very common in some animals. Ruminants were affected by pneumonia and pearl disease. Dogs had cirrhosis of the liver, syphilis was unknown in the lower animals, and so was gout, and cirrhosis of the liver, save in dogs, was almost unknown among them. Scirrhus was very rare in these animals, and epithelioma almost equally so. Drugs and poisons did not vary gradually in their action on various animals. They varied by leaps and bounds.

THURSDAY, AUGUST 9TH—THIRD DAY.

DR. WILLIAM MACEWEN read an address, taking for his subject some

RECENT SURGICAL INVESTIGATIONS

made by himself. He remarked that until recently the use of the trephine in surgery had been a most rare process, and confined to cases of traumatism. One reason for this was the exaggerated views imported into medicine as to the nature of the brain. As that organ was thought to be the seat of the soul, all attempts to interfere with it were considered as against morality. Nevertheless post-mortem experiences had shown, in many instances, that operations would, in all probability have succeeded in saving life if they had been attempted. But several points still stood in the way. Inflammations often proved fatal in operations on the brain in pre-antiseptic days, and in these days also diagnosis had not advanced far enough to enable the would-be operator to commence his task with sufficient hope. In 1870 Lister, in the Glasgow Royal Infirmary, by his experiments with antiseptics removed one of these obstacles, the chance of inflammation. Compound fractures of the skull were then easily and safely treated by trephining, and raising the broken fragment of the skull. Broca's great discovery of the locality of speech in the frontal convolutions showed that the various parts of the brain had their several functions, and that the brain did not, as was supposed, do all its work by the whole body of it. Dr. Robertson suggested that there were locomotive tracks in the brain; and a new departure was made after the experiments of Fritz and Hitzig in 1869. Ferrier's experiments on monkeys in 1873 gave the finishing touch to the inquiry, and soon abundant proof as to the localization of various lesions came from the observations of Professor Charcot. A case of

CEREBRAL ABSCESS

came before Dr. Macewen in 1876. The diagnosis was made that the abscess existed in the left frontal region. The parents of the child would not allow any operation to be performed and the child died. A post-mortem examination was made after performing the operation as it would have been had the child been alive. A trocar was introduced into the locality marked out, and pus at once flowed freely. This showed that had the operation been permitted the child might have been saved. Seven other cases were then detailed by Dr. Macewen. In one case a diagnosis was made of an abscess in the cortex of the right side of the brain, and on trepaning pus flowed, and the patient recovered. In his third case the lesion was diagnosed as occupying the frontal lobe, and that patient did admirably on the operation being performed after trephining at the spot indicated by the symptoms.

In the fifth case the diagnosis was made that a syphilitic tumor existed in the motor area. This tumor was excised, and the woman recovered perfectly. In Case VII. motor symptoms alone existed, and that case was correctly diagnosed and recovered under operation. All of these cases occurred before 1883. In December, 1884, the first operation of the kind in London took place, and the patient did well. The question whether the diagnosis could be accurately made from the localization of the symptoms might now be answered in the affirmative. Whenever possible, instruments of precision should be used instead of the unaided senses. Thus the dynamometer should be used to test the power of the muscles of the hand. In many cases the diagnosis of the locality was easy enough. Others occur in which there was a good deal of difficulty. In one case the patient, aged thirty-six, had one hundred fits in the day and had motor palsy of the tongue with paresis of the facial muscle and platysma, which were all occasionally subject to convulsions. Eight years previously the patient had had an injury in the head. Dr. Whitelock, of Glasgow, reminded him that the platysma muscle had a particular nerve from a certain locality in the brain. The skull was trephined acting on this supposition, and a cyst was found occupying the spot diagnosed. On incising the brain to remove the cyst a convulsion occurred, but this was the last, and when the patient recovered, no more such convulsions appeared. The arm remained paralyzed, and possibly the cyst had damaged the nerves of the arm. The lesion occupied the left cortical parietal region.

In another case, a girl, aged seven, had severe epileptiform seizures, accompanied with extreme pain localized in the toe of the right foot. This was accompanied by clonic convulsions of the muscles of that foot. The lesion was diagnosed to be cortical, and seated on the upper cortical region. It was concluded that it was tubercular. Operation was performed, and a tubercular tumor the size of a hazel-nut was removed. The patient got rapidly well and had continued in good health. Motor and sensory disturbances guided the diagnosis. A man had delusions and suicidal mania succeeded by terrible pain, which pain, however, he welcomed, because it removed the impulse to kill his wife and children. Immediately after an accident he had suffered from psychical blindness. Thus, he could not tell how many fingers he held up, although he could see them. He wanted to read the Bible, but on opening it he could not understand the words. The diagnosis was that the gyrus was affected. The trephine was used and a piece of bone removed from the region indicated by the motor symptoms and sensory symptoms. The man made an excellent recovery and was soon at work. Such cases of mental blindness he believed were very rare.

With regard to the idea of

REMOVING LARGE SLICES OF THE BRAIN FOR EPILEPTIC ATTACKS,

that was an operation that could not be commended because it tended to produce paralysis of one limb. Removal of an abscess was a totally different matter. Few epileptics would be found to prefer a life-long palsy to these fits. In cerebral surgery it was not enough to localize a lesion, its dimensions must be guessed at. In one case he operated on, the vessels were alone ligatured, as the lesion was too large to touch, and the case was much improved. As to the result of these operations, he had had twenty-one operations of the kind with three deaths, and those who died were in extremis when the operation was performed. Of the eighteen who recovered, sixteen were still alive and in good health. Two of them had died, one of Bright's disease, and the other from acute tuberculosis.

CERTAIN DISEASES OF THE SPINAL CORD WERE USEFULLY OPERATED UPON.

Some people objected to such operations, but they were in error. In one case of paraplegia, from angular curvature of the spine, occurring in a boy aged nine, there had been complete motor and sensory paraplegia. Plach's jackets were useless; the limbs were blue and cold, and urine and fæces involuntarily passed. The laminæ of the fifth, sixth, and seventh dorsal vertebræ were partially removed, and a fibrous neoplasm round the cord was removed, leaving the cord exposed. Twenty-four hours subsequently, the limbs became sensibly warmer, and eight days after the operation the urine and fæces could be voluntarily restrained. The boy now could play at foot-ball, and was quite well. In 1884 a poor girl appealed to him to operate on her for similar symptoms, and he removed portions of the laminæ of the dorsal vertebræ. Four days after the operation she could restrain the urine and fæces. In a year she recovered, and was now well and healthy.

Sir George H. B. Macleod then delivered the

ADDRESS IN SURGERY,

taking for his subject the progress of surgery during the last half century. He referred to the many great men who had lived and taught in the University of Glasgow, and to others, such as Cullen, Black, Hooker, Balfour, and Lister, who had begun their career there and had then gone elsewhere, like the wandering Scottish surgeons of the Middle Ages. The cause of learning had always prospered in Scotland, where one in six hundred attended the universities, while in England but one in five thousand avail themselves of that privilege. After reviewing briefly the progress of surgery during the first third of the present century, he spoke of the two

EPOCH-MAKING DISCOVERIES

of anæsthetics and antiseptics, which in the benefit they conferred upon mankind exceeded even steam and electricity. Concerning the choice of anæsthetics there was still some discussion, but the speaker used and preferred chloroform, which for ease of application, energy, and safety, when properly administered, was unrivalled. Anæsthesia has modified the whole of surgical procedure. The "lion heart" is no longer necessary to the surgeon, and skill and dexterity have taken the place of force. The use of

ANTISEPTICS IN SURGERY

was first made practicable in the Glasgow school. This has increased immensely the value of the surgeon's services. In medicine, also, it seems not improbable that, as a result of the study of the life-history and changes under cultivation of micro-organisms, all zymotic diseases may in time be stamped out. The experience of the Crimean War had led to the paying of greater attention to the construction and organization of hospitals, with the result of improving immensely their hygienic conditions. The speaker then referred to the advances made in operative surgery, and especially to the bloodless method of Esmarch and to the means of arresting hemorrhage by the aseptic ligature and by hot water. In orthopedic surgery the progress had been as rapid as in other branches. Plastic surgery, also, had recorded some of its greatest triumphs during the period under review. The methods of dealing with aneurisms had been multiplied, but their treatment had nevertheless been greatly simplified. In genito-urinary surgery the methods of treating stricture had been greatly improved, and the advances made in lithotrity and litholapaxy were such that the cutting operation might now be almost wholly restricted to cases in which the stone was of great size or extreme hardness. In the surgery of the female organs of generation the progress had been very great, and the same could be said of brain surgery and of the treatment of hernia. Indeed, in all the departments of surgical theory and practice the advances during the Victorian era had been immense, and his only fear was that he had not done justice to it in the limited time at his disposal.

THE PRESIDENT then presented a diploma of the Association, and a

GOLD MEDAL OF MERIT

awarded by the Council, to Dr. Ormrod, of Workington, who had at the utmost peril of his life descended a coal-pit and rescued many men who had been injured in a colliery accident.

FRIDAY, AUGUST 10TH—FOURTH DAY.

PROFESSOR MCKENDRICK then delivered an Address in Physiology, taking for his subject

PROBLEMS OF RESPIRATION.

He gave a most interesting history of the progress of opinion as to the method in which respiration was carried on, commencing with the views of Hippocrates and the ancients, who had no conception of the real facts of respiration. He then referred to the experiments of Sanctorius, professor of medicine in Padua, 1561 to 1636, who constructed a balance and constantly observed what he gained by food and lost by excretion. He stated that in twenty-four hours the loss of weight by the lungs amounted to about half a pound. Dr. Robert Hooke, 1635–1703, mentioned an experiment on respiration which he had made on a dog, where the thorax had been displayed by excision of the ribs and removal of the pericardium. This dog was kept alive by blowing up its lungs in an intermittent manner with bellows. Toward the end of the experiment he cut a piece of the lungs away, and observed that the blood freely passed into and circulated through the lungs, not only when they were kept fully distended, but also when they were allowed to collapse. This celebrated experiment showed that it was the fresh air, and not any alteration in the capacity of the lungs, which caused the renewal of the heart's beat. Hooke's experiment was of great practical result, as it suggested the modern practice of using artificial respiration in impending asphyxia. A gas might either be physically absorbed by a fluid, as was the case in water when the nitrogen and oxygen of the air which pressed on the surface of the water were taken up in certain definite quantities; or a certain amount of chemical affinity might be exercised by the fluids containing the gases, so as to enable them to take up more than water would do. The gases in the atmosphere pressed on the surfaces of fluids with a combined weight of fifteen pounds to the square inch. But the oxygen pressed with a pressure equal to its weight, *i.e.*, twenty-one per cent. of the weight of the atmosphere, while the nitrogen had a pressure of seventy-nine per cent. of the atmosphere on the surface of the fluids. In 1836 Magnus made some experiments with the blood, and came to the conclusion that carbonic acid and oxygen were merely dissolved in it in physical combination. Liebig, however, argued in favor of some chemical combination, and that Dalton's law did not hold in this case. Afterward Professor Kruger, of Bonn, showed that venous blood contained more carbonic acid, and arterial more oxygen.

The speaker then placed some ox-blood into long tubes containing various gases, such as oxygen, carbonic acid, nitrogen, and hydrogen, and, by agitating the fluid, he showed that in oxygen the color of arterial blood was at once assumed. His next experiment was to place some blood in a mercurial vacuum, and on collecting the gases given off it was found that carbonic acid was present by using the lime-water test. To show the presence of oxygen, he used a more powerful vacuum-producer, and, having collected a little gas, he introduced into it some solution of caustic potash, and next a solution of pyrogallic acid. This at once assumed a red color, showing the presence of oxygen in the gas. After these tests, which were shown with the greatest clearness to the audience, Professor McKendrick next proceeded to show how the spectrum was influenced by the presence of blood, and pointed out that there were two dark bands in the spectrum caused by the presence of that gas, which could be made to disappear by permitting the oxygen to be taken up by the hæmoglobin of the blood. After doing this, he again set free the oxygen from its combination with the hæmoglobin, and the dark hues at once reappeared.

After the passage of votes of thanks to the Lord Provost and magistrates of Glasgow, to the ecclesiastical authorities, to the professors of the university, and to various societies, committees, and clubs, the meeting of the Association was adjourned.

Correspondence.

MORE CONCERNING THE CATHETERIZATION OF WOMEN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Noticing the article, "To Facilitate Catheterization in Women," by Dr. S. E. Josephi, of Portland, Ore., in THE MEDICAL RECORD of August 18th, I wish to say that I have used the rubber tubing in the manner indicated for the past five years, and that I have recommended the use of the same to a number of professional neighbors. As I use the soft rubber catheter about ninety-nine times as often as I do the silver instrument, I will suggest the manner in which the rubber tubing is connected to the soft instrument, and which has been eminently satisfactory in my hands. Make the connection by slipping the distal extremity of the catheter over a section of glass tubing about two inches long and as large as the calibre of the catheter will admit, and then slip the rubber tubing over the other end of the glass, meeting the catheter about the middle of the inserted glass tube. I do not cite this as any remarkable discovery, and should not have thought it expedient to use your valuable space to delineate the procedure, had the article mentioned not given rise to the inference that such procedure was not common with the profession. Very respectfully,

E. J. BARNES, M.D.

HEBRON, O., August 25, 1888.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have read Dr. Josephi's note on his method of catheterization of women. I have for the last ten or twelve years adopted the same plan, and for the very same reasons, and with the same results. I claim no priority in the device—only that so far as *I* am concerned it was original, as it probably was with Dr. Josephi. It is a "wrinkle" that commends itself to the common sense of practitioners. I adopt the same method in tapping for ascites.

C. GREEN, M.D.

HOMER, N. Y., August 24, 1888.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: About the year 1873 a professional friend in Baltimore called my attention to this simple device, mentioned in your issue of August 18th by Dr. S. E. Josephi, of Portland, Ore. The idea was not new to me then, I thought I had invented the device some years before, but as he claimed it as original the matter was dropped.

In "Erichsen's Surgery," 1869 edition, p. 412, I find the following: "The catheter, which should be an elastic one, must be left in the bladder for a few days. It should not be plugged, but have a vulcanized india-rubber tube attached for the urine to escape as fast as secreted." My friend in Baltimore may have originated the device, your contributor from Portland also. I am sure the thought and application to save the gentler sex some shame and mortification was suggested to me by this item, treating upon wounds of the male urethra.

Dr. Josephi deserves credit for publishing the device in the columns of your journal; it will facilitate the work of the doctor and protect the feelings of the sensitive woman.

Permit me to add, life is dear, rubber tubing cheap and hard to clean. I direct the tubing to be cremated after use, burning it myself, if fire is convenient.

Respectfully,
J. M. WORTHINGTON, M.D.

107 CHURCH STREET, ANNAPOLIS, MD.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In a communication published in THE RECORD of August 18th, Dr. S. E. Josephi makes mention of the attachment of a piece of rubber tubing to a catheter when using that instrument to empty the bladder. The plan is a very good one and obviates many annoyances incidental to evacuation of the bladder, particularly after pregnancy. Dr. Henry R. Baldwin, of New Brunswick, N. J., called my attention to this simple procedure some five or six years ago, since which time I have hardly been without a piece of tubing to use at the bedside. I have heard that the idea is not a new one; but what is? So far, however, I have always considered Dr. Baldwin the originator, as I do not know who has a prior claim.

Respectfully yours,
WALTER LESTER CARR.

54 WEST THIRTY-EIGHTH STREET, August 20, 1888.

THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In view of the fact that frequent inquiries are made of the Committee of Arrangements, by medical men and others, in regard to the character of the organization now known as the Congress of American Physicians and Surgeons, which will hold its first triennial session in Washington, September 18th, 19th and 20th, it may be proper to state that several years ago the American Surgical Association passed a series of resolutions declaring it expedient that the special medical societies in the country should adopt some plan of organization by which they should be brought together at certain stated periods, and invited the other societies to co-operate with it in perfecting such a scheme. This invitation was accepted by the several societies, and in October, 1887, a committee of conference, composed of delegates from each of the societies, assembled in this city and agreed upon a plan of association, which was subsequently considered and accepted by the societies constituting the Congress as now organized. This plan consists simply of the agreement that the medical societies named shall hold their usual annual meetings at the same time in this city every third year, and that an executive committee, composed of one member of each society accepting the agreement, shall arrange for one or more general meetings for the consideration of such medical subjects by such physicians and surgeons as it may select, to be followed by such general discussion as time may permit. The present Executive Committee is also charged with the duty of devising and submitting a plan of permanent organization, which will be considered at a preliminary meeting on Tuesday morning, September 18th. There is no membership in the Congress proper. Membership belongs exclusively to the several societies constituting the Congress. Each society prescribes its rules for the admission of candidates, and transacts its business according to its own method. The Congress, as such, does not in any manner interfere with the autonomy of the several constituent societies.

The guests are men of distinction in some special department of Medical Science, who have been invited by some one of the constituent societies to attend its meetings, and perhaps to present a paper on some chosen subject. They are guests of a society, not of individual members. The Committee of Arrangements has not claimed or exercised the privilege of naming guests, nor has it conceded the privilege to individual members. At its suggestion the Executive Committee has invited the heads of the government bureaus of medicine, the president of the last International Congress, and several citizens to whom it was indebted for courtesies. In the event that there should be present from abroad any medical man who may not have been specially invited, the Committee will hold itself bound by ordinary courtesy to include him in the list of guests.

The meetings of the Congress and of the societies will be open to the profession. Any medical man who may choose to attend has the privilege of doing so; but the privilege of taking part in the discussions will be limited to the members, guests, and those who may be invited to do so by the societies respectively. The invitation to attend the meetings and engage in discussion will not, however, entitle one to the privileges of a guest.

Members and visitors must avail themselves of the ordinary excursion rates of railroad fare.

The Postmaster of this city has arranged facilities for the distribution of the mail at the office of registration, in Willard's Hotel. Letters must be addressed to "The Congress of American Physicians and Surgeons."

It may be added that the Committee of Arrangements declines to make any provision for, or to have anything to do with, any exhibit of pharmaceutical preparations and medical and surgical appliances.

I assume the responsibility of making the foregoing statement for the information of those concerned, and to avoid confusion and misunderstanding. And it gives me great pleasure to announce that the meeting in every respect promises to be a conspicuous success. Yours truly,

SAMUEL C. BUSEY, M.D.,
Chairman Committee of Arrangements.

WASHINGTON, D. C., August 27, 1888.

MR. EDITOR: Some complaints having reached the committee in regard to the distribution of invitations to the dinner to be given to the foreign guests of the Congress of Physicians and Surgeons, to be held in this city next month, I must beg the use of your columns to say that this distribution was in my hands.

The Council of the Congress having expressed themselves as averse to any elaborate entertainment on the part of the Congress, it may be said in the first place that this dinner is *unofficial*, and is in the hands of the *members* of the committee, and not of the committee. As it was necessary, after the matter was decided upon, to act quickly in order that proper invitations might be sent to Europe and answered in time, it was not possible to arrange this distribution so methodically as might have been done had the time been longer. It was intended that every member of the Congress, that is every member of any of the constituent associations, should have an opportunity to subscribe. Some circulars were sent directly by me, and some of them by such representatives of the association as I could most readily get at.

It is possible that there may have been some accidental omissions, and it is more than possible that at this season, when so many gentlemen are absent from home, some invitations may have gone astray. Another possibility, which we know to have been in some cases an absolute fact, is that they have been placed in the waste paper basket.

This note is intended as an invitation to every member of all the associations composing the Congress of American Physicians and Surgeons, who wishes to do so, to send his subscription of twenty dollars to Dr. S. C. Busey, 1545 I Street, N. W., Washington, D. C., for a dinner to be given at Willard's Hotel, in this city, on Monday, September 17, at 7.30 P.M.

I am, very respectfully,
ROBERT T. EDES.

WASHINGTON, August 21, 1888.

THE CLIMATE OF FLORIDA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue of the 11th inst. I see a reply from Dr. Lewis to my criticism upon Dr. Knight's conclusions with regard to the influence of the Florida climate upon consumptives. I have no desire to enter upon a lengthy or useless discussion upon the subject, and replied to Dr. Knight from a sense of duty. There is so much that is unsettled as regards the influence of climate upon consumption, that I would feel very happy if this one point could be definitely settled, even if it be proved that I am wrong; and I am pleased to hear Dr. Knight endorsed by so able an authority as Dr. Lewis. It strikes me that we are somewhat vague as to what extent of lung may be involved, and as to the intensity of the symptoms developed in the cases in question. Large cavities with severe hectic symptoms are often, if not usually, associated with general tubercular cachexia, and vital organs not open for exact physical examination already involved, particularly the stomach and intestinal canal, diarrhœa and indigestion being a frequent accompaniment of such symptoms. Nutrition is poor; there are pleuritic and intestinal pains; the individual is irritable and in no condition to enjoy anything. This is what I understand to be the condition in question. For patients with cavities and moderate hectic symptoms, fair digestion, and sufficient strength to get around, I am ready to admit that comfort and *perhaps* benefit may result from a residence in Florida. Such persons can engage in outdoor pursuits and enjoy our genial winter climate. But to even this class of cases, I think we should be cautious in expressing an opinion as to the benefit to be derived from such a visit. I have seen many persons come to Florida with "large cavities and severe hectic symptoms," and return disappointed as to themselves, and the record of the Florida climate injured because impossibilities had not been accomplished. I am happy to endorse all that Dr. Lewis says as to the effect of the Florida climate upon the various forms of bronchitis, pneumonia, etc.; but with all deference to the distinguished gentlemen who have entered into this discussion, I feel that I must still maintain my opinion as expressed in your issue of July 14th.

Very respectfully,
C. DREW, M.D.

JACKSONVILLE, FLA., August 22, 1888.

BATTEY *vs.* LAWSON TAIT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have just seen, on p. 646, Vol. 33, of THE MEDICAL RECORD, the following remarkable statement: "Dr. Battey said that he had modestly, too modestly, remained quiet, and had allowed Mr. Tait to talk about 'his operation,' for he despised this miserable quibbling about priority."

If Dr. Battey is serious in this utterance, why is he always raising the question and attacking me without the slightest provocation? In the *Atlanta Medical Journal*, June, 1887, Dr. Battey made an equally intemperate attack on me, to which I replied in the March number of the same journal. Dr. Battey must have read my reply. Permit me to quote the last sentence of it as a reply to the assertion of Dr. Battey, quoted at the beginning of this letter: "It is far better and wiser not to use such meaningless, and therefore such confusing, phrases. I say there is no such thing as 'Tait's operation,' and—on this side of the Atlantic—there is many a poor wretch who wishes there had never been heard of such a procedure as 'Battey's.'"

I have more than once expressed a strong objection in your own columns to the phrase "Tait's operation." I have never made any claim about an operation, and it is therefore diametrically opposed to the truth when Dr. Battey says I have talked about "my operation." He ought to discuss the principles upon which we operate, and not the persons who do the operation, and if Dr. Battey would spend half the energy in fighting those who oppose the progress of abdominal surgery that he directs against its friends, he might still live to do some great good in the world. I am, etc.,

LAWSON TAIT.

CHOLERA INFANTUM AND THE WEATHER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In a former short paper (MEDICAL RECORD, July 21st) I referred to a paper by Dr. A. Seibert, on the above subject, which specially interested me, because I had given considerable study to the disease referred to from a statistical point of view. I believe my work ten years ago, so far as the correctness of my tables is concerned, is substantiated by Dr. Seibert's work since. It would be very unfortunate, indeed, if Dr. Seibert's figures had contradicted mine, and I cannot avoid congratulating myself that, statistically, we agree. For these reasons I thought I might, in all honesty and gladness, characterize his paper as "a very valuable addition to tabulated facts bearing on this disease in its relations to the weather," while, at the same time, I refused to accept his methods of reaching certain conclusions, and rejected some of the conclusions he seemed to have reached.

I would offend the intelligence of the reader if I should undertake to show that there is *no* "inconsistency between this praise and fault-finding." I can trust the average reader to see that there is none.

Dr. Seibert's former paper, as well as his late one, and my little protest, being before the reader, I must apologize when I try to point out wherein his argument is "fallacious and misleading."

In the early part of his original paper (March 24th), in speaking of "monthly averages," he says "they are absolutely unreliable," yet he uses "monthly means," and even "means of the six summer months," to prove that "the frequency of summer complaint is independent of the rise and fall of atmospheric temperature." I submit that incompetent evidence cannot prove anything.

He then uses *daily maximums* to show that "very high temperatures do not favor the production of cholera infantum." I have already said "the fact that the thermometer indicates 80° or 90° F. for a moment, or a few minutes, does not make a hot day so surely as when the mercury takes a long rest at a much lower point."

He says, "we are now convinced that hot weather is not necessary" (this after a somewhat extended manipulation of *maximums*, leaving means and minimums out of the account), and directs his attention to a high minimum, and demonstrates the prevalence of the disease under consideration when the minimum daily temperature remains above 60° F. for a number of successive days. This is what he calls "*warm* weather," in contradistinction from *hot* weather. Yet we do not lose sight of the fact that with a persistent minimum above 60° we have a maximum almost always above 80° F.

A play upon the words "hot" and "warm" has no scientific value whatever.

He says "hot weather is not necessary for the epidemic appearance of summer complaint."

This is "misleading," because it *apparently* excludes the agency of high temperatures in bringing on the disease, which would be "in the teeth of his data."

His second conclusion, however, helps us out. “2. *Warm* weather, showing minimum daily temperatures of not less than 60° F., brings on the epidemic appearance of cholera infantum invariably,” but our attention is called *away* from the *daily maximum* in order, I suppose, to keep up the scientific distinction between “warm” and “hot.” The conclusion, however, is correct: “3. Summer complaint loses its epidemic character as soon as the minimal daily temperature remains below 60° F.;” the data sustain this. “4. THEREFORE this disease cannot be brought about by the direct working of high temperatures on the infantile body.” The present data prove the coincidence of persistent high climatic temperature and cholera infantum, the causative relation of the continued high temperature to the disease is substantially sustained by the data; but the question whether the infantile body is affected “directly” or indirectly cannot be absolutely settled by the present data. Yet, reasoning by exclusion, the presumption grows almost impregnable that cholera infantum is a *direct* effect of continued high climatic temperature on the child. The Doctor's *therefore* is “misleading,” because what follows does not grow out of either his data or his argument.

Again, Dr. Seibert kindly criticises me as follows: “If 75° to 80° F. is *hot* weather, then it is strange that so few cases of cholera infantum occur in midwinter, in this city at least; for it is well known that our tenement-house population, as a rule, keep their rooms constantly nearer to 80° than to 70° F. in the winter.” The ticklishness of this idea disappears at once when we reflect that it is a prostitution of the word “weather” to apply it to the reeking mixture of gases—hot or cold—found within the walls of a New York hovel. I am free to acknowledge that I was not aware that advanced pathologists had settled themselves finally in the position that diseases having features of resemblance (diarrhœa, for instance) are pathologically the same disease; but I rejoice in this apparent return to old time simplicity. As to the doctor's sarcastic reference to my remark that the diarrhœas occurring in the cold months are not pathologically related to the disease under discussion, I will allow the reader to judge whether the tapered end (I don't say point) of his sarcasm is more threatening to him or to me.

When Dr. Seibert adds up the July and August mortality in my Baltimore table and compares them, the result surely justifies my surprise that “great authorities” should have overlooked the superior mortality of July as compared with August, from this class of diseases, and I do not feel badly over this. I made no comment on the Baltimore table lest I might be tempted to *juggle* with the figures.

In the exuberance of easy mastery Dr. Seibert then exclaims: “If 334 children die in Baltimore in one month, then, surely, there are 334 *less to get sick* (italics his) the next month.” Just so; but there were 520 *births* in Baltimore in July, 1887, consequently, instead of “334 *less to get sick*,” there were, at least, 186 *more* to get sick. It is not always best to be so “cock-sure,” even on a self-evident proposition.

I suppose it was caution in this direction which led me to use such expressions as “I believe,” and “it seems to me,” etc., for which Dr. Seibert so kindly and patronizingly reprimands me. Yet such modest expressions never play such havoc with a man's viscera as abstruse operations in addition and subtraction are likely to do.

In conclusion, “it seems to me” that Dr. Seibert's statistics prove that *a continued, high, climatic temperature is the essential factor in the causation of cholera infantum*, and I am unable to see that his arguments prove anything else.

The ability to “add statistics” is an enviable acquirement, but the profession has a right to demand that the figures be honestly handled.

Having thus endeavored to pad my gluteal regions against the assaults of Dr. Seibert's disciplinary palm, I can only now express the hope that this friendly discussion may stimulate physicians to a more careful study of a most important subject.

T. CLARKE MILLER, M.D.

MASSILLON, O., August 17, 1888.

THE VAGINAL TAMPON.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In THE MEDICAL RECORD of August 18th Dr. Robert T. Morris describes “the perfect vaginal tampon,” and expresses his great satisfaction in its use. I have for some time made my vaginal tampons of wool and cotton, but I have not yet found what seems to me a perfect instrument, that is, a tampon that fills all the requirements for which this essential to gynecology is used. In the first place, no matter how you make the cylindrical tampon, or how carefully you place it, under certain circumstances it will become displaced, and thus, in a measure, defeat the object of its use. In the second place, a cylindrical tampon, from the very fact of its having a definite form, cannot be made to occupy and adapt itself accurately to the vaginal vault. The ordinary tampon answers some purposes very well, but it is to be regretted that many cases, in which nicety of fitting is essential, cannot be successfully treated by these cylinders of cotton, and still such cases clearly come within the range of those in which the vaginal tampon should be used. And while I agree with Dr. Morris that a combination of wool and cotton—one for its elastic, the other for its absorbent properties—makes, so far as material is concerned, the best tampon, I cannot agree with him in regarding the vaginal tampon which he describes a perfect one. I may say that latterly, both in hospital and private practice, I make my tampons of wool and cotton, but I have no one form in which I combine these materials; the essential, in my opinion, being to have the wool inside, and the cotton outside. Sometimes I find it best to use a piece of wool picked loosely, and laid in a small sheet of cotton, the two materials not even held together with a string. Such tampons I pack the vagina with, and find them very useful in holding the uterus in place. Sometimes I use the cylindrical tampon, but rarely compared with those tampons of no definite shape, believing that after the uterus is replaced the tampon should assume the shape of the vagina, and that if the tampon is used for its medicinal properties, uneven pressure should not be exercised upon the pelvic structures.

With the use of Dr. Wylie's solution (alum, ʒ ij.; boroglyceride, ℥ j.; glycerine, ℥ iij.), which Dr. Morris mentions, I have been disappointed. In my hands it has not only failed to relieve the pelvic and uterine conditions for which its author recommends it, but, in some cases, its use has been followed by so marked an aggravation of pain and local discomfort that I have discarded it from my list of local applications. Boroglyceride alone I find most useful; the same is true of alum, but in combination they have not afforded me the gratifying results that I was at first led to anticipate.

H. I. OSTROM, M.D.

42 WEST FORTY-EIGHTH STREET.

A VAGINAL TAMPON.—Dr. Frank Rattan, of Encinitas, Cal., writes: “The tampon as usually made has not been an entire success in my hands; it is rather difficult of removal by the patient. I have made and used one of late that I think is an improvement on any with which I am familiar. Take an ounce package of ordinary sheet absorbent cotton. It is about three and a half inches wide by half a yard long. Cut in half in two, lengthwise, and sew, with a sewing machine, a seam down the middle. This holds the cotton together like a strip of cloth. It is easily applied and easily removed.”

THE SIXTY-FIRST CONGRESS OF GERMAN NATURALISTS AND PHYSICIANS will be held in Cologne on the 18th to the 23d of the present month.

The Medical Record

A Weekly Journal of Medicine and Surgery

Vol. 34, No. 11 NEW YORK, SEPTEMBER 15, 1888 Whole No. 932

Original Articles.

REST IN THE TREATMENT OF CHRONIC JOINT DISEASE.

By JOHN RIDLON, A. M., M. D.,

ATTENDING ORTHOPEDIC SURGEON TO ST. LUKE'S HOSPITAL, NEW YORK.

REST may be defined as "a state of quiet or repose; a cessation from motion or labor." As applied to a joint, whose normal functions are motion and resistance to pressure, rest means a cessation from, or absence of, motion and pressure between the articular surfaces. We accomplish this by fixation or immobilization of those parts capable in any degree of producing intra-articular motion, by the removal of the superincumbent weight, and by the counteraction of muscular spasm.

Rest, in the treatment of chronic joint disease, does not necessarily imply rest in bed; nor does it imply a deprivation of sunlight and pure air; neither does the removal of the superincumbent weight necessarily imply the use of axillary crutches; nor the counteraction of muscular spasm imply the use of elastic traction.

Chronic joint disease I understand to be tubercular joint disease, unless otherwise specified. However the trouble may begin—as "traumatic" or "syphilitic," as "strumous," "scrofulous," or "fungoid"—it is at the first, or very soon becomes, tubercular; and it is only of this form of disease that I wish to speak.

Whether located at the ankle ("fungoid disease of the ankle-joint"), at the knee ("white swelling of the knee"), at the hip ("hip-joint disease"), in the spine ("Pott's disease"), or at the shoulder, elbow, or wrist, there can be no question that *tubercular disease* is the result of uniform or closely analogous laws of causation, and should be governed by like principles of treatment.

What, then, are those principles?

The early treatment of chronic joint disease seems to have had no very definite aim beyond temporarily relieving the sufferer. It consisted mainly of longer or shorter periods of rest in bed, and the local application of various medicaments. In 1834, Brodie[1] wrote: "But perfect quietude of the limb is always useful—always safe." In the following year, Harris, of Philadelphia, treated hip disease by fixation and traction, and rest in bed. He used Hagedorn's long splint. The weight and pulley, with rest in bed, but without any attempt at fixation, had been pretty generally used during the exacerbations in hip disease, when, in 1855, Henry G. Davis labored, and the "American method" of treating chronic joint disease was born.

Davis says:[2] "The treatment of Pott's disease and morbus coxarius should be founded upon this principle: Put the system in the best possible state, and remove all obstacles to the restoration of the parts. In Pott's disease we throw the weight, by means of mechanical support, upon the transverse processes of the vertebræ, and keep their bodies at their natural distances from each other; thus removing all pressure, and allowing the whole space affected by the disease to fill up with new material, thereby preventing the deformity which would otherwise take place. In morbus coxarius we separate the diseased head of the femur from the acetabulum, thus leaving the parts 'in a condition to recover so far as pressure might have interfered.' By this means we also get, in both instances, passive motion without friction."

Dr. Lewis A. Sayre[1] adopted the principles of Davis, and to his earnest and untiring work, both here and abroad, more than to anyone else, is due the advancement of the "American method."

Charles Fayette Taylor seems to have accepted the theory, but with some reservations. He did not adopt the "continuous elastic extension" of Davis, but used an apparatus for the hip, knee, and ankle that gave inelastic traction. At least that is my interpretation of Taylor's writings on the subject.[2]

Writing again, in 1867, Davis[3] says: "Most of the modifications of my instrument, made by others, have no guard in the form of an elastic band in the perineum."

This, we think, is sufficient to show that the *principle* of the "American method," as set forth by Davis more than a quarter of a century ago, and as adopted by Sayre and Taylor, and by many others, whatever their *practice* may have been, was "motion without friction," obtained by means of a "portative apparatus." And this is the "method" which is generally believed to dominate the treatment of chronic joint disease by American orthopedic surgeons of to-day. Upon what foundations this belief rests, it shall now be our effort to point out.

After a reasonably careful investigation, I have found but one surgeon who has made a consistent effort to treat chronic disease of all the joints upon the principle of free motion, elastic traction, and removal of superincumbent weight. I refer to Milton Josiah Roberts, of New

---

[1] Medico-Chirurgical Review, July—October, 1834, p. 34.

[2] American Medical Monthly, 1859, p. 361.

[1] In the American Medical Monthly, 1860, pp. 297, 298, Dr. Sayre says: "But the most important of all, and on which all prospect of success will depend, is *rest of the joint*, and *perfect freedom from pressure* of the synovial membrane. . . . I have treated a number of cases in this way, after the plan of Dr. Bauer, of Brooklyn, with the happiest results; using as a means of rest and extension his 'Wire Breeches,' an apparatus for the treatment of this disease, in some of its stages, which is far superior to any other I have ever seen or heard of. . . . I have, therefore, come to the conclusion that *perfect rest*, however essential it may be to an *inflamed synovial membrane*, is not only unnecessary to the ligaments, but was positively *physiologically wrong*. As the eye needs the healthy stimulus of light, so does the ligament need the stimulus of *motion*." In his Lectures on Orthopedic Surgery, New York, 1883, p. 269, he further says: "If patients are kept upon a straight splint, . . . and *extension* is maintained in addition to *fixation*, we will relieve our patients from suffering, it is true, and generally arrest the disease; but, unless the greatest care be observed, and in the later stages the patient be frequently removed from the apparatus and passive motion employed, it will almost invariably happen that anchyloses, more or less complete, will be left. . . . There are many cases in which inflammation is so violent, and pain on the slightest movement so intense, that *absolute rest* is required for a time. . . . But *motion* is as essential to retaining a healthy condition of the structure about a joint as light is essential to retaining a healthy condition of the eye. . . . I was led to contrive some plan by which extension could be maintained that would remove pressure from the acetabulum and head of the femur, and at the same time permit motion of the joint."

[2] In Mechanical Treatment of Hip Disease, New York, 1873, pp. 14, 15, Dr. Taylor says: "We find, then, from our premises as well as from clinical experience, that it is *pressure*, or motion *under pressure*, which is the destructive agent in disease of the hip-joint. Hence we derive our two prime indications for mechanical treatment: 1st. To relieve the pressure in the joint due to muscular contraction by temporarily destroying the muscular irritability and contractility. 2d. To protect the joint from weight and concussion.

"*The indication for arresting motion in the joint*, which is well met with the gypsum bandage and similar expedients, *pertains only to a condition of rigid muscular contraction, and consequent increased constant pressure in the joint. But no such necessity exists after the muscular rigidity has been overcome to the degree of entirely removing all pressure from within the joint.* On the contrary, motion without pressure is not only not injurious, but is highly beneficial.'

[3] Conservative Surgery, by H. G. Davis, p. 214, New York, 1867.

York. I do not say he has succeeded, but I do say that he has made a consistent effort, and that his latest apparatus—with box-spring, elastic traction, and woven wire corset—is an admirable apparatus of its kind, and gives one who believes in the principles of Davis no excuse for continuing the use of Sayre's and Taylor's apparatus.

Without any change in the *principles*, we find that, in *practice*, Dr. Sayre uses, for tubercular disease at the ankle and knee, apparatus evidently intended for traction and immobilization;[1] at the hip, a traction apparatus which we are told allows free motion without friction;[2] and in Pott's disease, apparatus that is intended for fixation of the lower dorsal and lumbar spine, while it only removes superincumbent weight in the upper dorsal and cervical spine. This has been more fully referred to by another.[3] In a recent paper,[4] however, we find an apparatus advocated which gives traction and fixation of the patient from his head to his heels.

Dr. Taylor, on the other hand, has very considerably modified his principles and practice, although he uses substantially the same apparatus as he did twenty or more years ago. He does not any longer "believe in the desirability of 'motion without pressure' while inflammation is acute and progressive, using fixation with counter-extension in such cases."[5]

These views, however, are so well and fully stated in Dr. Henry Ling Taylor's paper on the "Hygiene of Reflex Action," that I make no apology for quoting therefrom:

"The spasmodic condition of the neighboring muscles, resulting from the stimuli of the irritated tissues in progressive joint disease, presents a condition opposite to the one discussed. We cut off locomotor stimuli, in the acutest cases, by putting the patient to bed for a month or six weeks, and eliminate, so far as possible, by counter-extension the specially irritating and damaging stimuli occasioned by the rubbing and pressing of the inflamed surfaces. When the recession of the inflammatory action is fully inaugurated, we allow locomotion, with the weight borne on the perineal strap of the counter-extension splint, which takes the pressure from the joint and does not permit the foot to touch the ground, using crutches also if necessary. In the recovering stages it is desirable to permit a certain amount of stimulation, in order to promote nutrition, before the joint can safely bear pressure; we therefore give the joint motion, the amount of which is regulated by proper stops on a jointed apparatus, which still suspends the leg and carries the weight on a perineal strap. In this way the amount and kind of reflex stimulation which the leg receives is carefully regulated according to the indications. The withdrawal of stimulation causes muscular weakness and wasting, which is favorable to the joint in the active stages of disease, but the muscles improve as the joint recovers and the stimuli are readmitted. It is thus seen that bracing a paralyzed leg and a diseased one have entirely different objects and results."

Most of the followers of Taylor, among whom can be found some of the most celebrated orthopedic surgeons in the country, use his original forms of apparatus, and hold the theories and principles which he promulgated more than twenty years ago. With these, "exercise in the fresh air" is the one thing of prime importance; and rest in bed, even for a short period, is dreaded and avoided whenever the patient can in any way manage to get about on his hip-splint.

It would be neither a pleasant nor a profitable task, at this day, to follow down the shifting sands of principles and practice from Davis to the present time. Only two figures in this country stand out with sufficient prominence to seem worthy of especial mention: A. B. Judson, of New York, and De Forest Willard, of Philadelphia.

Judson teaches that all chronic joint disease, affecting no matter what joint, should be treated by fixation and removal of superincumbent weight. And, unlike most of the followers of Davis, he has consistently endeavored so to fashion his apparatus as to attain that end. We do not feel sure, however, that he has accomplished this at the hip. Although his apparatus is far more effective as a fixative apparatus than that of Sayre or Taylor, it is, nevertheless, a long-traction portative apparatus. He believes that traction is an effective means of fixation, and cites a long list of authorities,[1] in support of this view. It does not seem to have been recognized that, at the hip, traction gives fixation only when unopposed by voluntary motion, and when sufficient to overcome involuntary muscular contraction. The following clinical facts seem also to have been overlooked: That a patient in whom there is free, painless motion through ninety degrees, can, while wearing a long traction-splint, flex the thigh on the pelvis to that degree; that flexion, abduction, and adduction not infrequently supervene while the patient is wearing the apparatus, either walking or in bed; that the majority of patients treated by this apparatus recover with the leg flexed and adducted; and that it is possible for subluxation to take place while the patient is wearing the apparatus and resting in bed in a well-cared-for orthopedic hospital-ward.

Of Willard's teaching, I cannot do better than quote the following:[2] "The application of rest as a principle in the treatment of joint disease, although very generally accepted, is yet frequently employed only as an adjuvant of other means of relief, while its proper position is in the first rank, and other means are but subsidiary. . . . Those who advocate the 'motion-without-friction' cure assert that motion is the normal condition of a joint, which statement, while true in regard to normal articula-

---

[1] It has not been demonstrated, however, that the apparatus gives any degree of traction upon the bones; and it is certain that it does not immobilize, because it aims only to control the *bones* which go to make up the articulation. To immobilize the ankle, and the muscles that give motion at that articulation, it is necessary to immobilize the knee; and to immobilize the knee, it is necessary to immobilize the hip and ankle. A glance at the muscular attachments will make this evident.

[2] We believe that Dr. Sayre now uniformly uses the long traction-splint. This apparatus is practically the long traction-splint of Taylor, with an elastic, instead of an inelastic, hold-back strap. The Taylor splint is used by many (Shaffer, Judson, and Gibney) to obtain fixation, and although, as it seems to us, it gives neither free motion nor absolute fixation, it certainly is fixative to a very considerable degree during locomotion. During eight years of active orthopedic work in New York City, it has not been my fortune to meet with one patient wearing a Sayre *short* splint.

[5] In a private letter, in answer to a question on my part, Dr. Taylor's son, Dr. Henry Ling Taylor, writes:

"No. 201 WEST FIFTY-FOURTH STREET,
"NEW YORK, July 11, 1888.

"MY DEAR DOCTOR: You will find the best account of my father's views on 'fixation vs. motion without friction' in the first part of his paper entitled, 'Observations on the Mechanical Treatment of Disease of the Hip-joint,' Boston Medical and Surgical Journal, March 6, 1879. You will find references also in the 'Mechanical Treatment of Disease of the Hip-joint,' William Wood, 1873. Especially at pp. 53 and 54, and the end [?] of Chap. vi., and in the article on the 'Mechanical Treatment of Synovitis of the Knee-joint,' New York Medical Journal, July, 1873, pp 1, 2 and 11 of reprint.

"I have alluded to the subject from another point of view in a paper on the 'Hygiene of Reflex Action,' pp. 9 and 10 of the reprint (Journal of Nervous and Mental Diseases, March, 1888).

"The considerations in the above references apply, with proper modifications for local conditions, to most of the joints of the body, but the mechanical relations in the spine are so different that the same considerations do not apply. Then the only safe principle we believe to be fixation with leverage, progressively modified.

"Very sincerely,
"HENRY LING TAYLOR.

"P. S.—You will see from the references that we do not believe in the desirability of 'motion without pressure' while inflammation is acute and progressive, using fixation with counter-extension in such cases."

[2] De Forest Willard on Joint Diseases: Treatment by Rest and Fixation, New York Medical Journal, December 5, 1885.

tions, is no more applicable to diseased ones than to inflamed muscles or other tissues. . . . The surgeons who strive most earnestly to obtain a cure with motion are the ones who are obliged to perform the most resections. Decide upon the instrument that will give the most absolute rest, and you will make the best cure. The indications are to fix the joint, protect it from injury, maintain proper position, and yet be light and comfortable. . . . To sum up in outline: 1. Rest reduces joint inflammation more effectually than all the other means combined, often aborting, always lessening, an impending process. Its employment is indicated by nature; its beneficial influence is seen in every domain of medicine; in theory it is rational, in practice it fully proves its power. 2. The more perfect the rest, the greater will be the diminution of pressure, friction, tension, and inflammation, and the less will be the resultant anchylosis and suppuration. 3. The means of securing rest and fixation are exceedingly simple, and can easily be applied by every intelligent practitioner."

Ten years before this, Hugh Owen Thomas, of Liverpool, had first given to the world a system of treating chronic joint disease by fixation. He says:[1] "The treatment introduced to the notice of the profession, in this volume, may be summed up as a combination of enforced, uninterrupted, and prolonged rest; the first gives relief from pain; the second, added to the first, enables the case to steadily progress to a cure; and the third secures that which has been gained." Writing again in 1883, he says:[2] "No writer on, or teacher of, surgery has hitherto advanced any consistent theory with regard to the treatment of articular disease, this being perhaps the cause of the very patent fact, that the mode of practice in the cure of joint disease still remains so varied and divergent. Consequently, as soon as a surgeon reaches a position of vantage where he has opportunities for the treatment of unhealthy joints, he almost invariably introduces a specialty of practice behind which he soon intrenches himself, and from which no amount of reason or evidence is likely to dislodge him."

It has been said that the best commentary upon the "American method" is the remarkable frequency with which its principal advocate has had to perform excision of the hip-joint. It should also be noted that the same gentleman seems to have been seldom called upon to excise those joints which he treats by fixation; and the infrequency of his hip excisions during the past ten years. Dr. Sayre has, since 1854, excised the hip seventy-three times; sixty-nine of these operations were from 1859 to 1879, inclusive.[3] When this is compared with the work of Thomas, who has never found a case demanding excision when treated by proper fixation, and of Judson, who in twenty years' practice as an orthopedic surgeon in New York has "never performed 'the majestic and sanguinary' operation,"[4] it demands the careful consideration of all, whether motion or no motion should be our guiding principle.

Eighteen years ago Dr. Sayre, that Apostle Paul of the New Dispensation, went abroad and did "missionary work"[5] among the heathen. The "method" was tried and universally abandoned. *Thirteen* years ago Thomas first published his theory of treating joint disease by rest and fixation; and the assertion that this is "the old English method which has been tried in this country and found useless," is as absurd as it is false. Among modern surgeons, who take into consideration the pathology of the disease, there are but two modes of treatment: the operative, which seeks to remove at once and completely the tubercular material, and that by rest and fixation. Nearly all who have written on the principles of the treatment of tubercular joint disease during the past three years, have advocated rest and fixation. Besides De Forest Willard, already quoted, we may mention: Henry A. Reeves,[1] Edmund Owen,[2] Herbert W. Page,[3] Howard Marsh,[4] C. N. Macnamara,[5] G. A. Wright,[6] Robert Jones,[7] and V. P. Gibney.[8] This shows the trend of modern orthopedic surgery. So far as I know, no rational explanation has been given for the treatment by rest, other than that each, working for and by himself, has learned the lesson from clinical facts. I will therefore venture to offer the following suggestions, which may indicate the way we are to go:

Motion between two contiguous surfaces implies friction, and the greater the pressure, the greater the friction. Friction implies increase of temperature; and the greater the friction, the greater the increase of temperature. A healthy joint has a slightly higher temperature immediately following exercise than before; and a tubercular joint

[4] Private letter of Dr. Judson, August 13, 1888.

[5] Dr. Sayre in Europe: New York Medical Journal, 1871, pp. 219 and 435.

[1] "The indications to be fulfilled by these machines are (1) to support the diseased portions of the spine, (2) to remove superincumbent weight, and (3) to prevent increase of deformity."—Bodily Deformities, by Henry A. Reeves, p. 141. London, 1885.

[2] "The mechanical treatment of spinal caries is comprised in one word, *rest*. . . . Plaster-of-Paris jackets, and other forms of support, aim at securing rest while the patient goes about, but this is only the second-best line of treatment, for the rest is less perfect. . . . Rest, and always rest, is the one indication for the treatment of these cases. . . . The treatment [of hip disease] will vary somewhat with the stage to which the disease has advanced, but the principles are unchanging; they are the insurance of absolute and uninterrupted rest for the joint, and correction of the bodily deformity. . . . When in bed the child should *never be allowed to sit up*. . . . Every case of hip-joint disease should from the beginning be treated by means of Thomas' splint. . . . Any splint designed to allow some movement at the joint during the treatment must be wrong in principle and unsatisfactory in practice. The demand for absolute rest for the inflamed joint is as urgent as is the absolute darkness to which the patient with acute retinitis is consigned."—Surgical Diseases of Children, by Edmund Owen. Philadelphia, 1885.

[3] "Whatever be the special plan adopted, one principle, and only one, should underlie it, and that is to secure *rest* for the spinal column. . . . In the early stages of the malady. . . . before deformity exists, whether the disease is slow or acute, or whatever its site, the child should be kept absolutely at rest in bed."—Herbert W. Page on Pott's Disease, in Manual of Surgery, edited by F. Trevis. Philadelphia, 1886.

[4] "Rest, to be efficient, must, as far as possible, be absolute, so that the joint is never moved. . . . The American surgeons have introduced splints intended to secure extension while the child is still allowed to move actively about. These are models of inventive ingenuity, and the object which they are designed to fulfil (that is, of conducting the treatment without confining the patient to the horizontal position) is highly desirable. These splints, however, after having been fully tried, have been generally discarded by English surgeons, on the ground that, not only is it impossible to maintain extension (that is, prevent intra-articular pressure) with them, but that they do not secure adequate fixation (that is, rest) of the joint. . . . It has been found that the mere maintenance of the horizontal position, even for one or two years, in good air, has no prejudicial effect on the general health, and that it is only where confinement is combined with pain and suppuration that the health suffers. Under these circumstances the mortality of hip disease, adequately treated, has fallen from about thirty to five per cent."—Diseases of the Joints, by Howard Marsh. Philadelphia, 1886.

[5] "Probably there was nothing that so forcibly struck those who visited Liverpool at the meeting of the British Medical Association, as the hip-joint cases under Mr. H. O. Thomas' care. Patients in all stages of the disease were shown us. . . . the hip secured by means of his valuable splint and with clog to raise the other foot, so as to preserve the diseased bones from pressure. With crutches such patients could get about, and under treatment of this kind the greater number of these were doing wonderfully well."—Diseases of Bones and Joints, by C. N. Macnamara. London, 1887.

[6] "In the earlier stages of the disease there is a general agreement among surgeons that rest, immobility, and time are the main features in a case. . . . Thomas' apparatus is a very valuable appliance, and is undoubtedly the best splint we have for patients able to be up. . . . The splint is of use in the early stages of the disease, when it is possible to give the child the chance of long-continued and perfect rest with general hygienic measures."—Hip Disease in Childhood, by G. A. Wright. London, 1887.

[7] At a meeting of the Liverpool Medical Institute, January 19, 1888, Mr. Jones, by request, showed upward of twenty cases of chronic joint disease that had been treated by fixation from two to four years. Very many had had the joints laid open, and nearly all had had abscesses; nevertheless all had very considerable motion. Provincial Medical Journal, March, 1888.

[8] "My plea this evening shall be for absolute immobilization of a diseased joint. . . . Rely, therefore, for relief, both from abscess and deformity, upon fixation of, and protection to, the joint."—V. P. Gibney on Diseases of the Knee and Elbow, New York Medical Journal, March 17, 1888.

shows the same conditions in a considerably increased degree. The advocates of the "American method" have sought this increased temperature because increased nutrition is associated with increased local temperature, and have ignored the fact that the inflammatory process is also associated with increased local temperature. They have also advocated motion as a means of maintaining the nutrition and strength of the muscle; and have ignored the fact that the stronger the muscle the greater the muscular spasm and consequent intra-articular pressure. On the other hand, the advocates of rest and fixation have admitted that they were willing to starve the joint; that they sought muscular atrophy and weakness as a means of reducing muscular spasm and intra-articular pressure; and that their treatment lowered the nutrition and the temperature of the joint. This they accepted as being opposed to inflammation. Since, however, it has been established that we have to deal with a tubercular process, a reasonable explanation appears for the heretofore empirical treatment. It has been shown that if the local temperature about a tubercular lesion be raised from two to eight degrees, the tubercular process increases proportionately; and that if the general temperature be increased and maintained for a certain time, the process becomes rapidly fatal. So, also, in animals upon whom inoculation experiments have been made; the law is well recognized that the higher the normal temperature of the animal, the less resistance is there to inoculation, and the more surely fatal the result. The observations of Brush[1] show the normal temperature of the horse to be 99.2° to 100.3°; dog, 99.3° to 101.9°; cow, 100.8° to 101.8°; guinea-pig, 102°; rabbit, 103°; common fowl, 106.7°. Now, if you compare this table with all the recent inoculation experiments on bovine tuberculosis, you will find that the success of such experiments is in direct ratio with the temperatures—that is, commencing with the lower temperature, that of the dog, we will find the resistance lessening as we go up the scale, till we come to the common fowl, with the highest temperature, when there is no resistance whatever. Feeding with tubercular matter is always positive with this bird. Professor James Law gives the temperatures as follows: Horse, 99.5°; dog, 99.5°; cow, 102; and chicken, 107°. There seems to be no doubt that increase of local or general temperature favors the deposit and development of tuberculosis; and there appears an explanation why, without any hereditary taint, tuberculosis of the joints is so often found among the sequelæ of the fevers of childhood, and is so often the unfortunate termination of a prolonged elevation of local temperature due solely to traumatism.

If we may then assume that increased local temperature favors the development of tuberculosis in a joint, the converse should also hold, that a lowering of the local temperature, to or below the normal, hinders or checks the tubercular process, and all the destruction and danger that depend upon it. *Rest*, as defined at the beginning of this paper, does this. It reduces the temperature to or below the normal; it prevents the destructive process of friction; it removes intra-articular pressure from superincumbent weight and muscular spasm; and it relieves pain, and thereby restores normal sleep and normal appetite. Pure air and sunlight, as well as proper food, are things much to be desired, but they do not appear to be of such importance as absolute rest to a joint.

To recapitulate.—The theory of motion in the treatment of chronic joint disease was the result of the old fear of anchylosis; but we have not found recorded an authentic case of anchylosis due to the immobilization of a tubercular joint.

Motion with traction followed necessarily; because no patient could endure motion without traction, unless anæsthetized.

A portative apparatus became a necessity, because patients treated by motion with traction died, unless they had the benefit of good air and sunlight.

The results of the use of the Davis and Sayre splints, or modifications of them, which are claimed as allowing motion, have not been published, although they have, in some form, been in use for thirty-three years.

Motion, as a factor of the treatment of disease of the joints other than the hip, has been universally abandoned; and there appears no good reason why it should be continued at the hip, or in tubercular synovitis of the knee.[1]

Motion without friction between joint surfaces is obviously a mechanical impossibility.

The Taylor and Judson splints came to take the place of the Davis and Sayre splints because they permitted less motion at the hip-joint.

The results of the use of the Taylor splint as a portative apparatus leave much to be desired.[2] It does not prevent rigidity, flexion, abduction, adduction, and shortening, either from erosion or subluxation.

All long traction-splints of which we have cognizance give interrupted instead of "continuous" traction during locomotion; and interrupted traction, while muscular spasm exists, implies motion.

Continuous traction can only be maintained by placing the patient in bed, or upon a patten (under the well leg) sufficiently high to prevent either the foot or the splint from reaching the ground. In practice this is not done.

All short splints that depend upon adhesive plaster, as other similar means for tractive power, fail to prevent intra-articular pressure and motion during locomotion, unless crutches and a high patten be used.

Continuous, uninterrupted traction relieves pain and aids the correction of the deformity in very many cases. In a few cases, however, it causes pain and muscular spasm; and there is much evidence that it can be dispensed with in all cases, provided fixation and removal of superincumbent weight be efficient.

Fixation is necessary in all cases; it must be continued without interruption until the inflammatory process has subsided; and the more perfect the immobilization the quicker and the better the result.

Removal of superincumbent weight must be absolute from the beginning of treatment until the end of convalescence.

Thomas' splints, for the hip, knee, and ankle, are the most effective, known to the author, for inducing fixation. Many, however, have failed in using them, because they have caused their patients to walk about before the muscular spasm had subsided, because they frequently removed them to "test motion," and because they failed to use a patten sufficiently high (four to six inches).

The use of efficient fixative apparatus combined with a longer or shorter period of rest in the horizontal position, absolutely insures a cure, without other deformity than shortening in all joints except the spine; and in the spine it insures against any increase in the curvature, and a diminution and absolute reduction of the curve in very many cases, and, not infrequently, freedom from rigidity.

We are inclined to think that the dangers to the general health from confinement to the horizontal position have been exaggerated, and depend upon unfounded assertion and observation of cases treated without, or with but imperfect, fixation.[3]

In cases of hip disease, after a cure has been effected and the fixative apparatus removed, we favor the use of a modification of Dr. Taylor's Dows-splint, as more convenient and safer for young children than the crutches and patten.

A CASE OF LEPRA NERVORUM.[1]

By JOHN LORD BABCOCK, M.D.,

DEMONSTRATOR OF ANATOMY IN THE BEAUMONT MEDICAL COLLEGE, ST. LOUIS.

THERE is probably no disease in the whole dismal category of diseases of which so much has been written, and about which such diverse theories have been spun, as leprosy, the most ancient of them all; and there is that in its slow onward march to an inevitable death that may well have filled the mind of ancient and mediæval man with unpitying horror. The very name to most men yet possesses all of the chill dread of ancient days, and I cannot pretend to say how many people in our city would consider it almost suicidal to sit in a street car with a leper.

The history of leprosy from the day when it was considered the curse of God, down through the period of the four cardinal humors of the blood, to the day of the lepra bacillus, would epitomize the history of medicine; but of this long and fascinating story this is neither the time nor the place to treat. I wish first to direct your attention to a few remarks on the subject of leprosy in America.

Leaving out of consideration for the present the disease as existing in Central America, Mexico, and certain of the West India islands, I will limit myself to the endemic foci of the disease in the United States and Canada. The very few and very puzzling cases of the so-called sporadic type I cannot now speak of.

The best known nidus of leprosy on this continent is that near the Bay of Chaleur, in New Brunswick, where a lazaretto has been in existence since 1844.[2] There were in this institution, in 1887, sixteen patients, and six were known to be outside. According to the report of Dr. Taché, Government Inspector, the number of lepers in the district is steadily diminishing, a change which he concludes to be commensurate with the carefulness of the segregation and the improvement in the moral and hygienic surroundings of the people. These cases are about evenly divided between the anæsthetic and tuberculous types, and are chiefly of interest to us on account of the possibilities suggested by the escape of an inmate of the Tracadie lazaretto, who, after a period of unrestrained wandering in New England, finally turned up in Professor White's service in the Massachusetts General Hospital, where for the first time his condition was diagnosed.

There are a few cases of leprosy to be seen from time to time in the principal eastern seaports, which. as far as known, except in the case of Charleston, S. C., are imported from places where the disease is endemic.

In Charleston,[3] between 1847 and 1882, there had been sixteen indigenous cases, including none but positive types.

In Louisiana the history of leprosy is unique and very instructive, and is of special interest to us as bearing on the case in hand. Dr. Jones[4] quotes Gayerre as saying, in his "History of Louisiana," that there were many lazarettos in that province during the Spanish régime of the last century. In the latter part of that century, however, and the early part of this, leprosy gradually disappeared in Louisiana, and the lazarettos were therefore closed and ultimately destroyed. No further cases were reported, and leprosy seems to have been practically unknown there until 1866, when a certain Madame Ourblanc, in Vermilion Parish, whose father had come from Southern France, was observed to be suffering from lepra tuberosa of a very pronounced type. In her case the tubercles ulcerated very extensively and with comparative rapidity. She had four sons, three of whom subsequently had leprosy, the fourth being lost track of. She had also two daughters, one of whom died of an acute disease, the other of leprosy. Up to 1878, there were also developed three other cases connected directly with that of this Madame Ourblanc—one being that of her nephew, another her nurse, and the third a young man who was reported to have slept for some time with one of her sons. Besides these there were several other cases reported in various parishes in the southern part of the State, near New Orleans, Dr. Salomon[1] placing the whole number in 1878 at fourteen. Dr. White[1] reports having a leprous native of Louisiana under his observation in Boston in that year. Dr. Rohe[2] is quoted as giving the history of an American woman who went from Baltimore to New Orleans in 1855, remained in and about the latter place until 1866, when she returned to Baltimore. She developed leprosy in 1869, and died in 1878 or 1879. From a consideration of all of these cases, we must infer that, in and about New Orleans, there is some agency at work which has caused more cases in that part of the country than can be accounted for by the simple fact that New Orleans is a seaport.

There were, up to 1879, twenty-six cases of leprosy reported in Minnesota, Wisconsin, Iowa, and Nebraska, among the Norwegian and Swedish immigrants, who are so numerous in those States, and in whose native land the disease is endemic. Among these, perhaps the most interesting is that of a child, born to a leprous father, which in 1879 was reported by Dr. Hyde[3] to be suffering from tubercular leprosy. If this is true, this is the first case reported in the United States in which the disease has developed in a native child. There have been also several cases reported among the Chinese in California and Oregon, but in regard to these no statistics are attainable.

In St. Louis there have been reported up to date two cases of leprosy, and both within a year. The first of these two was reported by Dr. Hardaway, the case being that of a Chinaman, now in the City Quarantine. The second case was reported by Dr. Ohmann-Dumesnil, at the meeting of the Missouri State Medical Society, in April last, this case being that of a woman who died in June, 1887, from "an uncontrollable diarrhœa." I believe I have the honor to report the third case.

No remarks are ever made on leprosy nowadays, without there being included an expression of their author's opinion as to the infectious or contagious character of the disease.

The first case of leprosy I ever saw was an inmate of Charity Hospital, New York, where he was subjected to no restrictions other than those relating to all the patients in the hospital. The next case I saw while an assistant to a dermatological clinic in New York. This man I saw brought before a general class of students by Professor Piffard, several times. We have no less an authority than Kaposi himself for such treatment of these cases. Dr. Keber tells me that Kaposi had three lepers in his wards of the Vienna General Hospital last year, who were treated on the same footing as all the other patients. Kaposi states:[4] "All experience teaches that leprosy, although very probably based on a bacterial infection, is not, or at most except under very special and rare circumstances, a contagious disease." And again he says:[5] "Leprosy is probably, under special circumstances, contagious, but much less so than syphilis, and there must be presupposed a direct and repeated introduction of the products of leprosy by immediate contact and injury of the skin." I cannot better sum up this part of my subject than by quoting the four conclusions of Neisser,[6] as follows: "1. The bacillus lepræ is the cause of each case of leprosy. 2. The proof of heredity has not been made. 3. The possibility of a direct contagion is without doubt, yet the danger and probability of it are very slight. 4. The existence of spore forms allows the possibility that, without

direct contagion from man to man, the infection can take place, but man is to be considered the chief carrier of the virus of leprosy."

The case I have to report to you this evening is that of James B——, married, a native of Ireland, who came to this country at the age of two years, coming directly to St. Louis. He is now forty-one years of age. His family history, as far as attainable, is good.

He himself always enjoyed the best of health until 1866, when he had what he calls a mild attack of yellow fever, in New Orleans, a few months after arriving there, having left St. Louis in that year for the first time.

The next two winters he spent driving a street car in New Orleans, and worked during the summers in a sawmill on the eastern shore of Lake Pontchartrain.

During the next ten years he travelled between New Orleans and St. Louis, spending most of his time in or near the former place, his occupation being that of a mechanic and carpenter. For the last three years prior to 1879, he lived continuously in New Orleans. In 1871 he had a slight attack of gonorrhœa, lasting three weeks. He gives no other history of venereal disease. In 1876, he suffered for eleven months from "swamp fever" on the shore of Lake Pontchartrain. In 1878, he found employment in New Orleans as a yellow fever nurse, and again in 1879. In the fall of that year he returned to St. Louis, where for a time he worked in our Quarantine, which at that time contained yellow fever patients. Since 1879, the man has lived continuously on North Twentieth Street, in our city.

In March, 1881, he noticed that several red spots, about the size of a silver quarter of a dollar, appeared quite suddenly on his face, accompanied with intense itching and burning. On the 18th of that month he was seen by a physician, told that he had erysipelas, and sent to the City Hospital, where he remained until June 20th. The hospital record[1] of the case is as follows: The diagnosis was "Erysipelas (?)." "James Brennan, Ireland, aged thirty-four, admitted March 18th, idiopathic erysipelas of face and arms. Had an elevation above right eye, very red, which varied at different times in height. Under iron internally and fl. ext. ergot topically, erysipelas soon disappeared.

"April 26th.—Patient transferred from erysipelas ward to ward 7 (devoted to skin diseases). The red blotches on the patient's face remained after his transfer. They were painted at different times with iodine and fl. ext. ergot, but these applications seemed to have very little effect. Patient complained also of pains in the soles of his feet, for which we could find no apparent cause. In hope of benefiting this trouble he was given potassium iodide internally and his feet painted with iodine. These remedies, however, have very little permanent effect.

"May 10th.—The red blotches still remain in the face. They are not painful. His principal complaint now is the pain in his feet, more particularly the dorsum following the tendons. Continued the iodide; used no local applications.

"June 20th.—Patient transferred to Dr. G. and was discharged." The patient says that since his discharge from the hospital the pain and numbness in his feet and hands grew better at times, but that they never felt natural, and were painful most of the time, particularly in cold weather. He says that the color of these original red spots gradually faded, and after "about a year" they became distinctly brown, and have remained so ever since. During the last six years he has lost thirty-five pounds in weight, and his strength has gradually left him, so that he has been unable to work at all during the past year and a half. He has been married five years. His sexual desire and power have gradually failed, so that now he has had none of either in two years. On January 17, 1884, he was readmitted to the City Hospital, the records this time showing that the left great toe and all of the right toes were superficially frozen. Discharged February 1st. In July, 1884, a large bulla, filled with bloody serum, appeared on the left great toe, near the point of injury by freezing. This bulla was ruptured, and now a hard cicatrix, ulcerating slightly at two points, marks the spot. Four years ago he noticed that his eyelashes and eyebrows were coming out. The man says that, about a year after he left the hospital the first time, while shingling a roof, he noticed that he could not tell, without looking, whether or not he was holding a nail in his fingers; since then he has gradually lost the feeling in his hands, but he adds—"I am very easy hurted in my back."

The patient says he made several visits at a large dispensary in this city in February and March last, where he was treated ineffectually for a "sore throat" and a "cold." He thinks his sense of taste is not as good as formerly, and he has had no sense of smell in years.

The man came to me on April 20th, to consult me about his general condition, but chiefly in regard to the state of his mouth. I found a destruction of the mucous membrane of the roof of the mouth and of the pillars of the pharynx. I was at a loss to account for such an extensive ulceration, but, be it confessed on general principles, I put him on increasing doses of the iodide of potassium. At his first visit I made no special examination. At his next visit, I questioned him more closely, discovered the general anæsthesia of the hands, examined his face, and made a diagnosis of leprosy. I referred him to Dr. Mulhall, the laryngologist, for an expert examination of the mouth. The doctor suggested a gargle of 1 to 5,000 bichloride, which was ordered and used with happiest effect. Dr. Mulhall writes: "I found in the case you mention great thickening of the septum narium, as well as of the lateral cartilages, so as to produce considerable stenosis. No ulcers existed in the nose. The hard and soft palates, and the anterior and posterior pillars of the fauces, were covered with small shallow, discrete, serpiginous ulcers resembling very much tubercular ulceration." Since that time the man has been seen with me by Dr. Hardaway and Dr. Keber, and on Sunday last I reported him to the Health Department, and he was sent to the City Quarantine.

In order to definitely differentiate in regard to syphilis, I still continued the treatment referred to above, adding $\frac{1}{16}$ gr. bichloride thrice daily. I increased the iodide, giving it in saturated solution drop doses with infusion of gentian. At ninety grains he rapidly developed iodism, so that the dose was reduced to and continued at sixty grains, at which he scarcely tolerated it.

This treatment was kept up systematically for three and one-half weeks, with the result of making his general condition worse and not alleviating a single symptom—unless the improvement of the mouth was due to that rather than to the antiseptic wash, which is not very probable.

His condition at present is as follows: His hair is coarse and thick, beard thin and scattering. He has complete ciliary and supra-ciliary alopecia. His nose throughout is very much thickened, as are his lips. On the right cheek he has an irregular area of white, apparently cicatricial, tissue, and another similar area over the right eye. In the supra-orbital regions of both sides, particularly the right, he presents irregular hypertrophic masses, which, with the absence of the eyebrows, give a peculiar prominence to the forehead, suggesting the condition known as contiasis. Scattered over the face, except in the whitish areas referred to, are many small tubercles varying in size from that of a small shot to that of a pea, one of the largest of which is over the left eye. The skin of the face has a very muddy, faintly maculated appearance, and has a harsh, dry feel. The glands at the angles of the jaw are very much enlarged and are very firm, those on the right side forming a solid confluent tumor. The post-cervical glands are not perceptibly enlarged. The condition of the mouth and nose have been already referred to. His hands present very marked atrophy of the thenar muscles. The palmar surface is covered with a very much thickened skin, which in both hands is ulcerating slightly at several points about the ends of the fingers and palms. The grip of his hands is very much weakened, and there are scattered about, particularly on the dorsum of the hand, a great many small tubercles lying close under the skin. His hands, especially the fingers, always felt cold when I examined them, and their lividity indicated the inefficiency of the circulation. At the middle of the inner surface of the right arm there is a firm, movable mass under the skin, about the size of an almond. The axillary glands are enlarged.

---

[1] From the records of the St. Louis City Hospital, kindly furnished me by Dr. Dalton, surgeon in charge.

On all the surfaces of the trunk are irregular maculæ, which are of a distinct yellowish-brown color, contrasting very markedly with the normal color between them. There are two of these spots over the region of the tenth, eleventh, and twelfth ribs, on the right side, which are perfectly round and distinct; the others are more or less irregular in outline, some having a distinct border and others shading off gradually. Some of these maculæ are covered with a fine, furfuraceous desquamation.

The glans penis presents an irregular, hardened mass lying around the meatus, not being raised above the surface, and extending from it for about one-third of an inch. The inguinal and femoral glands are very much enlarged.

While the maculation just described extends down the arms irregularly to the elbows, it does not extend down the leg. The feet have upon them a very few tubercles, and a large, firm, fissured, whitish cicatrix on the left great toe marks the location of the bulla referred to above. He has a varying, but constantly present œdema of the legs and feet, which, however, is never very marked. On his right leg, about six inches above the ankle, are three ulcers, covered with dry scabs and surrounded by brown pigmentation, suggesting an old tertiary syphilide in appearance.

His symptoms referable to the nervous system are as follows: His sense of taste is impaired, and the sense of smell seems to be destroyed. He has an area of anæsthesia, about the size of a man's palm, in the region of the angle of the jaw on the right side, and the sensitiveness of the skin of the face generally, as measured by the æsthesiometer, is very much diminished. He failed to distinguish the two points of the instrument at two inches, the normal point of separation at which they are appreciated being a little less than half an inch for that region. The ulnar side of his right hand has complete superficial anæsthesia extending one-fourth the distance up the forearm to the elbow. The radial side of the dorsum of this hand, as well as the finger-tips, are faintly sensitive to strong irritation. The left hand is completely anæsthetic, and the anæsthesia extends half way to the elbow. He is unconscious of the pricks of a pin or a knife which draw blood, and only experienced slight pain during the excision of a large tubercle from this hand, when I passed a needle deep into the surrounding tissues, while stitching up the wound. The æsthesiometer indicated a complete loss of tactile sensibility in the whole of the left forearm. In this arm the ulnar nerve is very perceptibly and irregularly enlarged, and at its passage over the internal condyle it is as large as a lead-pencil. There is marked hyperæsthesia on the dorsal surface of the body. The man winces and complains at a very slight pressure. There is, however, no increase of the tactile sensitiveness indicated by the instrument. Neither of the man's feet is wholly anæsthetic, although sensation is very dull in both. In both upper and lower extremities he suffers from sharp, stinging, but not constant pains. No enlargement of the popliteal nerve could be detected.

To sum up; the points of interest in the case are as follows:

1. The prolonged history beginning with what Bidenkap, of Christiania, calls the "polymorphous exudative erythema," or the erythema multiforme of Hebra, which resists all treatment, and gradually fades into macular discoloration, together with the acute, long-continued, lancinating pains.
2. The steady increase of atrophy and anæsthesia through a long period.
3. The tubercles, small and large, including the supra-orbital bosses.
4. The marked localized hyperæsthesia.
5. The loss of weight, of special senses, of sexual power, and the ciliary and supra-ciliary alopecia.
6. The glandular swelling and the swelling in the nerves, and lastly, the bacillus, without the demonstration of which the correctness of my diagnosis might be questioned.

I removed from each of this man's hands a tubercle, that from the left hand being about a fourth of an inch in diameter. The smaller tubercle was examined hastily by the teasing process, being stained with methyl violet and decolorized with a mixture of hydrochloric acid and alcohol. Thus prepared, the fragments of tissue were found to be swarming with bacilli, morphologically resembling the tubercle bacillus. This process, however, was merely confirmatory, and absolute demonstration was not reached until the other tubercle had been mounted in celloidin and carefully cut and stained, in which manipulations I had the valuable assistance of Dr. Keber. The bacilli were thus seen *in situ*, crowding certain of the cell-elements, and being also distributed in the tissues without apparent reference to the cell-bodies. I hope to be permitted to demonstrate these bacilli to the Society at some future meeting.

306 North Compton Avenue.

URETHRITIS, ACUTE CYSTITIS, OBSTRUCTION OF THE URETER, HYDRONEPHROSIS, ULCERATION THROUGH THE PERITONEUM, DIAPHRAGM, PLEURA, AND LUNG-TISSUE, AND DISCHARGE OF FLUID THROUGH BRONCHI—RECOVERY.

By Z. T. SOWERS, M.D.,
WASHINGTON, D. C.

The patient, white, male, aged nineteen years, scientific plumber, when two years old began to have periodic attacks of pain, which were presumed to be "stomachache" or "colic." The application of cloths wrung out in hot water usually afforded relief in the course of an hour or so. These paroxysms of pain would occur three or four times a year.

After the child had experienced three or four of these attacks his mother began to notice that his side would swell each time these recurred, "like a ridge between the hip and lower ribs." Under these conditions, an hour or so after the use of the hot applications, he would urinate freely, the ridge would disappear, and he would be free from pain.

When the patient was six years old he was seen by a homœopathist, who pronounced the trouble "inflammation of the spleen." He was under homœopathic treatment for some time.

After coming to Washington he was brought under the observation of a regular practitioner, who pronounced the trouble "neuralgic pains in consequence of the large vein passing through the kidney becoming congested."

Hot applications, in addition to morphine and camphor internally, were prescribed, which always gave great relief. But the relief was only temporary, and desiring a permanent cure they consulted another physician—this time a homœopathist again. Finally the patient drifted into my care, with such results as are indicated in the following lines:

On November 20th the patient called at my office, and was found to be suffering from an attack of specific urethritis. The usual well-known remedies were administered, and with the usual result. Rest had been particularly urged. Nothing out of the ordinary routine of such cases occurred until the 29th of this same month. On the 29th of November, being summoned to see the patient at his home, I found him suffering from cystitis and also bronchitis. Simultaneously with the appearance of the cystitis the urethral discharge ceased.

At this time pain in the region of the spleen and along the course of the ureter (left) was complained of, and, in consequence, hot applications were ordered.

The pain persisting, morphine was administered, and the patient subjected to dry-cupping, and this, in turn, followed by blistering. The granular effervescent lithiated potash was administered very freely.

The quantity of urine being passed during this time amounted to one quart in the twenty-four hours.

A microscopical and chemical examination of the urine at this time, by Dr. D. K. Shute, showed the presence of a very large number of leucocytes, triple phosphates, bladder epithelial cells, and granular débris; also the presence of albumen; no tube-casts; no epithelial cells from pelvis of kidney; no sugar.

In consequence of necessity, the patient had not been able to comply with my recommendation as to rest. He was compelled to work at his occupation—scientific plumbing—in a rather damp place, which latter especially induced his bronchitis. The ordinary remedies for bronchial and vesical inflammation were administered, and followed by satisfactory results. The patient was visited daily. On December 10th a slight fusiform enlargement was noticed in the left lumbar and inguinal regions.

The patient was seen daily by me until December 19th. During this time the tumor was continuing to enlarge very much. The mere fusiform shape of the tumor during this time was becoming less and less noticeable, but on the 19th there was present a large bulging tumor extending from the crest of the ilium to the ribs, and from the lumbar around through the left inguinal and the hypogastric regions to the median line, even encroaching, to some extent, upon the right segment of the abdomen. Fluctuation at this period was easily detected. The constitutional symptoms at this time, as throughout the whole period of illness of the patient, were very slight. No chills, no sweats, scarcely any elevation of temperature.

On December 19th Dr. S. C. Busey was called in as consulting physician, when it was decided to use the aspirating needle for purposes of exploration.

The clinical history of the patient revealing the fact that previous enlargements had suddenly disappeared simultaneously with copious discharges of urine, it was decided in consultation to await developments for awhile.

Consequently, on December 20th and 21st, consultations of observation, if I may use such an expression, were held. On the 22d the parts had become so much distended that, after consultation with Drs. S. C. Busey and D. K. Shute, aspiration was deemed imperative.

Even at this time there was scarcely any constitutional disturbance. The patient being anæsthetized I introduced one of Dieulafoy's large-sized aspirating needles (after a preliminary incision had been made through the integument and fasciæ) midway between the umbilicus and the anterior superior spine of the ilium, carrying the point of the needle obliquely upward, outward, and backward. The needle penetrated the sac of the tumor with great difficulty, in consequence of its great toughness and unyielding nature. One gallon of bloody fluid was withdrawn, which, when subjected to examination by chemical analysis and the microscope, revealed the following characters: A trace of albumen; alkaline reaction; sp. gr. 1.020; a large number of blood-corpuscles; a few spindle-shaped epithelial cells, etc. Unfortunately no examination was made to detect the presence or absence of urea.

On December 22d, prior to the aspiration, the urine was normal in color. That voided after the operation was bloody-looking—resembling very much the fluid drawn by aspiration. This latter fact inspired the hope that, probably, the obstruction being removed, the sack would not refill—and this hope was still further strengthened, inasmuch as there was no apparent increase in the size of the sack, and the amount of urine now being voided amounted to three pints (one pint in excess of what it was previous to the operation). These favorable conditions obtained for four days. During all this time, again, there were no constitutional symptoms. On the fourth day, however, there was a very perceptible refilling of the sac. The amount of urine passed this time amounted to over one quart—still bloody. On December 26th, after consultation with Drs. S. C. Busey, D. W. Bliss, and D. K. Shute, it was decided again to aspirate the patient. Local anæsthesia, by means of cocaine, being very satisfactorily induced, the sac was again aspirated, and one gallon of bloody fluid removed, resembling that previously withdrawn, but being much richer in blood corpuscles, as revealed by the examination made by Dr. Shute. After the tapping a large compress was applied over the sac, and retained in position by Martin's elastic bandage, with the hope that they would aid the expulsion of the fluid and prevent its reaccumulation.

On December 27th consultations were held, and the patient found in excellent condition. On the 28th there was no consultation. On the 29th a consultation was held. No reaccumulation of fluid apparent. Patient in excellent condition.

On January 1, 1888, the fluid was evidently accumulating again, presenting a swelling about the size of an orange, which gradually increased until January 5th, when it reached the dimensions of a small cocoa-nut and remained stationary until January 12th. No pain or fever during this time. Scarcely any soreness in the region of the "tapping" or of the spleen.

On January 11th I saw the patient about six o'clock in the evening, and found him suffering with symptoms of acute indigestion—flatus causing dyspnœa, palpitation of the heart, and a pronounced hacking cough, which were greatly relieved for a time by the application of turpentine stupes and the administration of stomachics.

The symptoms continued to some extent until 12 P.M., when the cough became very violent and was accompanied by the sudden expectoration of about half a pint of frothy, bloody fluid, very similar in appearance to the fluid that had been drawn by aspiration previously, as indicated by microscopic examination. Simultaneously with this expectoration was the complete disappearance of the cocoa-nut swelling and the unpleasant symptoms, such as dyspnœa, etc. The patient, to use his own expression, "thought he had coughed the lump up;" no pain during all this time.

On January 12th I saw the patient, in consultation with Drs. Busey, Bliss, and Shute. We found him in a comfortable condition; temperature, 99° F.; pulse, 100; no pain.

Physical exploration revealed absolute flatness over the entire lower lobe of the left lung and half of the upper lobe. Entire absence of vesicular murmur. No bronchial breathing. A very large number of moist râles were audible in the upper lobe.

The first urine voided after these occurrences was now found to be perfectly clear. And the quantity voided in the twenty-four hours became very large, averaging more than half a gallon, and was normal in appearance.

The fluid expectorated was subjected to chemical and microscopical examination, and found to be like that drawn from the sac by aspiration in all essential respects. A fact of special interest to note is that this fluid was slightly alkaline in reaction.

On January 13th the expectoration continued, still bloody, though much diminished, and the constitutional symptoms continued to be insignificant. The lung gradually cleared up from above downward. There were a large number or moist râles throughout the whole lung.

January 14th.—Gradual improvement; less cough and sputa; less blood in the sputa; lungs were clearing up very rapidly.

January 16th.—Improvement very marked. Lungs entirely clear except at a very small portion of the lower part of the lobe.

January 19th.—Consultation for "scientific inquiry." Lung entirely normal.

January 22d.—Patient called at my office. He had been out riding for one hour in a cab.

January 25th.—Patient went to a ball and danced several hours.

March 7th.—Slight irritation about the neck of the bladder. Passed a slight concretion of uric-acid crystals. Lithiates were administered.

March 10th.—Patient entirely well.

April 12th.—Left for Denver, Col., to reside.

In commenting upon the clinical history of this case, the first inference that necessarily thrusts itself upon my mind is, that there must certainly be a congenital constriction of the left ureter, low down toward the bladder.

The frequent attacks of pain and swelling in childhood, which were, upon the use of hot and counter-irritant applications, relieved, with the simultaneous discharge of large amounts of urine, point, in my judgment, quite surely to this conclusion.

The constriction must have been of such a nature that ordinary "colds," by inducing internal congestion, must have so engorged the mucous membrane of this left ureter as to cause complete occlusion of this small channel of exit for the urine.

In explanation of the tremendous enlargement present in the patient during this last attack, we have the two potent factors—cold, causing congestion, and therefore great swelling of the mucous membrane of the ureter in the neighborhood of the constriction, and, probably a more efficient cause, extension of the inflammation to the congenitally weak point, in consequence of the acute cystitis.

The simultaneous occurrence of these two factors produced such intense inflammatory swelling that the procedure which had been formerly so successful now utterly failed; so that the three influences—continued excretion of the urine (to be referred to shortly), complete obstruction of the channel of exit, and thirdly, both of these conditions obtaining for several days—all conjoined to bring about the tremendous enlargement present at the time of aspiration.

It will be noticed from the clinical history that the color of the urine, previous to the operation, was normal where, after the operation, the urine became bloody—very much resembling the aspirated fluid. How is this to be accounted for? I think as follows:

The inflammatory swelling of the ureter in the neighborhood of the constriction had very much subsided at the time of the operation, so that, as far as this factor was concerned, the urine (bloody) in the dilated ureter (dilated above the point of constriction, of course) was capable of flowing onward into the bladder; but, prior to this subsidence, the bloody urine had accumulated to so great an extent in the dilated ureter that now the element of mechanical pressure was superadded as an obstructing cause.

Of course, when the mechanical pressure was relieved by aspiration the bloody urine from the left ureter was allowed to flow down into the bladder and discolor the clear urine in the vesical organ which had been coming from the right (and healthy) ureter.

A very interesting fact to be noted from the clinical history of this case is that, previous to the aspiration on December 22d, the patient had been passing two pints of clear urine and after the aspiration three pints of bloody urine, which suggestive fact seems to indicate that the left kidney was not only not destroyed by pressure, but, on the contrary, was performing its function quite effectively. Moreover, since one gallon of fluid was withdrawn by the second aspiration, which occurred four days after the first one, the kidney was secreting daily one quart of urine.

Another interesting fact to account for is the presence of blood in the aspirated fluid as well as in the urine after the operation. Evidently, again, the clinical history furnishes a very satisfactory explanation.

On the night of January 11th the patient, after a paroxysm of violent coughing, expectorated a considerable amount of bloody fluid, closely resembling that drawn by aspiration—there occurring at the same time a complete disappearance of the swelling in the side. Evidently an ulcerative process had been going on for some time in the sac as well as through the diaphragm and related structures, in consequence of pressure, which ultimately permitted the contents of the dilated ureter to break through the diaphragm into the lungs. This ulceration was the source of the blood which discolored the urine in the diseased ureter.

Now what explains the fact, noted in the clinical history, that after this occurrence on the night of January 11th, the first urine voided was perfectly clear? It must be this: Simultaneously with the progress of the ulcerative process there occurred localized adhesive peritonitis as well as pleuritis, which prevented the pouring of the contents of the sac into the cavity of the peritoneum or that of the pleura. When the sac ruptured the ulcerated portion was carried by the force of the escaping fluid a sufficient distance into the perforation to subject it to considerable pressure. This pressure was sufficient to control the flow of blood from the open blood-vessels into the fluid contents of the sac; consequently there was no more blood to discolor the urine in the dilated ureter or in the bladder; the bloody expectoration, which continued for a few days, with slight coughing, being accounted for by the ulcerated tissue.

Probably the most interesting fact to observe in the clinical history of this patient is the entire absence of pneumonia after the contents of the dilated ureter had broken into the lung. We know that normal urine is a most irritating fluid. In extravasation of urine from any cause, the most violent inflammation is excited in parts reached by this fluid. It is this fluid that prevents successful plastic operations upon the penis where the mucous membrane of the urethra is involved, etc. Why is it, then, that the urine in this left diseased and dilated ureter did not excite inflammation in the delicate tissue of the lungs? We confidently expected pneumonia of a violent type to occur. How could we do otherwise *à priori?* But neither pneumonia nor any other inflammatory condition arose.

I think the following is the explanation:

It is a well-known fact that all the nutritive processes of the body take place in alkaline fluid. The tissues of the lungs are constantly bathed in alkaline fluid—the plasma of the blood—a fluid which is bland, soothing, and life-sustaining. We have already noted that there was hemorrhage into the contents of the dilated ureter. This hemorrhage was quite profuse, entirely sufficient to impart to the urine a pronounced alkaline reaction. Therefore the fluid that came in contact with the delicate lung-tissue was not the acrid, irritating, acid, normal urine, that does so much harm, but urine that had become perfectly harmless and soothing by being made alkaline in consequence of the large amount of blood contained in it.

I have already stated that the ulcerated portion of the sac was forced into the opening in the diaphragm, and subjected to pressure by which further hemorrhage was prevented. It was by this same means that any of the after-forming acid urine was prevented getting in contact with the lung-tissue.

Very plainly, the clinical history of this case will exclude the presence of pyonephrosis or pyelitis, and just as plainly points to hydronephrosis. Moreover, it indicates a case of hydronephrosis the pathological conditions of which are of long standing, and one in which, strange to say, the kidney had not been destroyed by long-continued (though intermittent) pressure.

ON THE HYDROBROMATE OF HOMATROPIA AS A MYDRIATIC FOR DETERMINING ERRORS OF REFRACTION.

By S. G. DABNEY, M.D.,

PROFESSOR OF PHYSIOLOGY AND CLINICAL LECTURER ON DISEASES OF THE EYE AND EAR, HOSPITAL COLLEGE OF MEDICINE; VISITING SURGEON TO EYE AND EAR DEPARTMENT, LOUISVILLE CITY HOSPITAL, LOUISVILLE, KY.

Says Landolt (p. 310, "Refraction and Accommodation of the Eye"): "We very seldom have recourse to atropization for the determination of astigmatism." Fox and Gould ("Diseases of the Eye"—Quiz Compends): "Astigmatism is an invisible and elusive imp of mischief, requiring much keenness and patience to hunt him down. His hiding-place is the ciliary muscle; his disguise, amblyopia. He hates atropia as his father was said to hate holy water. There can be no accurate and exhaustive diagnosis of refractive errors without the use of a mydriatic." The majority of oculists, those in America at least, I take it, are in accord with the authorities last quoted, and must have been surprised at the opposite opinion from so high a source as the distinguished ophthalmologist of Paris. It behooves us, then, to select that mydriatic which will produce most thorough suspension of the accommodation. Our choice for this purpose usually lies between a solution of sulphate of atropia and a solution of the hydrobromate of homatropia. Though the latter is often more convenient for the patient, in that its effect is of so much shorter duration, yet it is often insufficient. Not only may it be impossible to find any correction which will raise the sight to the standard of $\frac{20}{20}$, but, what is still more likely to mislead, we may have perfect vision after its thorough instillation, and be led to believe that no glass is required, or we may find V $\frac{20}{20}$ with a plain spherical, and yet its use be unsatisfactory. It has been my custom to use a fresh solution of the homatropia, of a strength of one grain to the drachm, procured from a druggist of the best repute, and of this to put two drops in each eye every ten minutes in the hour preceding the examination; this method is pursued in all refraction cases in persons under forty-five or fifty years old. In the majority of cases it has proved satisfactory, but in a considerable number it has been afterward found necessary to use a solution of atropia, and I become every day more inclined toward the exclusive use of the latter drug to suspend the accommodation, notwithstanding the inconvenience caused by the long duration of its effects. This inconvenience is largely counterbalanced by the enforced rest thus obtained, often an important element of treatment in itself, and by the greater ease with which the eye becomes accustomed to the appropriate glass.

The following cases are sufficient to illustrate the above remarks; though I might add many others, I think it best to give only a few of typical character:

Case I.—Mr. K——, aged twenty-four, applied to me, January 21st, on account of frequent supraorbital headache and shooting pains through the head; the headache always followed any attempt at reading and any exposure to bright light, and was so severe as to compel him to leave college in Virginia and return to Louisville. He was referred to me by Dr. Franck C. Wilson, of this city. I found each eye possessed V $\frac{20}{20}$ and refused the weakest + glass. After the most careful use of homatropia in the manner above described, V still $\frac{20}{20}$, and no hypermetropia manifest. A few drops of a solution of sulphate of atropia (gr. iv. to ℥ j.) were then instilled and repeated the next morning; examination an hour after the last instillation showed V of each eye scarcely more than $\frac{20}{30}$, and each brought to $\frac{20}{20}$ clear with + .5 D cyl. ax. 90°. These glasses were directed for constant use; the gentleman returned to his college duties, and, as he informs me by a letter recently received, suffered no more from headache or painfulness to light.

Case II.—Miss W——, aged thirty, subject to pain in and over the eyes. Eyes feel tired and objects become blurred on close work. Each eye, $\frac{20}{30}$; Hm + .5 D. Under homatropia best sight obtained with + 1 DS, which gives $\frac{20}{30}$ +. Under atropia + .5 DS $\bigcirc$ + .5 D cyl. ax. 90° $\frac{20}{20}$ clear. These glasses were directed for constant use and relieved the asthenopic symptoms.

Case III.—Dr. H——, aged twenty-one, dentist, complains that his eyes hurt him and objects become blurred after close work; interferes seriously with his operations at the dental chair. V. each eye, $\frac{20}{20}$, and in each Hm of .75 D; the same under homatropia, no glass stronger than this allowing perfect vision; +.75 DS was ordered for constant use and was worn for about six months, when the gentleman returned complaining of the same symptoms, though in less marked degree. Examination under atropia now revealed a hypermetropia of 1.5 D, and its full correction gave entire relief.

Case IV.—Miss P——, aged eighteen, school-girl, finds it impossible to continue her studies from the severe headache induced by any attempt at reading or exposure to bright light. V, each eye, $\frac{20}{70}$, and each brought to $\frac{20}{20}$ with — 1.5 DS; the same condition under homatropia. These glasses were worn first for distance only, and later constantly, but with only partial relief of her disturbances. The patient returned after eight months, saying that she still suffered from headache on any attempt to read or sew. The atropia solution being instilled, the proper correction was now found to be — 1 DS $\bigcirc$ — .5 D cyl. ax. 180°; these glasses giving vision of $\frac{20}{20}$ clear, while those prescribed under homatropia now gave only $\frac{20}{30}$ +. After six weeks' use of the combined spherical and cylinder the young lady returned to say that her headaches had disappeared and she could read, sew, or otherwise apply herself to close work without annoyance.

TUBERCULOSIS TREATED BY TANNIN.

By S. DE JAGER, M.D.,

NEW YORK.

I find in The Medical Record of August 4th a report of the treatment of phthisis by tannin. As I myself have used tannin in some cases of pulmonary tuberculosis, it will perhaps be useful to mention the results. A second reason of my speaking about this subject is that, according to what is reported about it in the *British Medical Journal* of April 7th and June 11th, it would seem that this treatment was first introduced by the Italian professor Leccherelli, of Parma, and afterward by Dr. De Viti Demano. I have not the original articles of these authors at my command, and therefore cannot say whether they refer to two French investigators, Raymond and Arthaud, who, more than a year ago, introduced this treatment after experimental researches on animals.[1]

These two investigators tried to find out whether it would be possible to bring into an animal some substance in such a way that tuberculous virus would have no effect if it were injected in the same animal afterward. After some fruitless attempts with iodoform and other things, they tried tannin, as, according to Gohier and Bouley, animals which were fed with tannin did not putrefy after death. They gave rabbits one gramme (gr. xv.) of tannin mixed with their food, during one month or less. Then they were killed and placed in an incubator in which the air was moist and warm. The cadavers were kept in it during a fortnight without the slightest putrefaction.

Encouraged by these results, they inoculated rabbits with tuberculous virus after having fed them with tannin during some time, so that their tissues were, as they call it, saturated with tannin (tannisés). Rabbits which were inoculated with tuberculous virus at the same time, but without being fed with tannin, died of tuberculosis, while those saturated with tannin were still quite healthy. The experiments were also made on patients. A quantity of five grammes (℈iv.) of tannin was given every day to patients suffering from pulmonary tuberculosis, and Raymond and Arthaud saw that, soon after the beginning of the treatment, the symptoms diminished, the cough, the night-sweats, and the general weakness became less, and after a fortnight those whose lesions were not too severe had gained in weight, which gain continued during the further treatment.

---

[1] Raymond et Arthaud: Sur les moyens de rendre l'organisme réfractaire à la tuberculose. In the 1st volume of Verneuil's Études expérimentales et cliniques sur la tuberculose.

They conclude that tannin brought into the body must have some anti-bacillary effect, though they admit that their experiments do not prove in the least whether tuberculosis can be cured by it or not. After these experiments it seemed to me worth trying, and so I have used tannin in five cases of pulmonary tuberculosis. One case lasted only five months, and in this, my first trial, it was not possible to give even small quantities of tannin. Vomiting followed directly after taking it, so that I soon stopped this treatment. In the other four cases the patients are all in an advanced stage of the disease, but I am quite satisfied with the effect of the tannin. My experience in these cases does not entirely agree with those of Raymond and Arthaud. I could not detect any influence on the cough or expectoration, nor was there any lasting effect on the night-sweats. But the great advantage of using tannin is the perfect regulation of appetite, digestion, and bowels. Two of the patients came to me in a very weak condition. There was no appetite, the bowels very very irregular, now constipated, now loose. Soon after taking tannin the condition improved immensely. The bowels became quite regular and are still so, in one case after five months, in the other after six weeks, and though formerly they could eat hardly anything, not even take a drop of milk, their appetite and digestion are quite good now and they take large quantities of boiled milk with pleasure. Is it a wonder that patients gain somewhat in weight under such circumstances?

I give the acidum tannicum purum in capsules of 0.25 gm. (gr. iv.) each, and begin with one capsule three times a day, one hour before meals. After a week I change the quantity and give three capsules of 0.50 gm. (gr. viij.) each daily, and increase every three or four days with one capsule a day, till the patient takes two capsules five times a day. If, sometimes, nausea follows, a piece of dry bread taken directly after the capsules seems to have a good effect. I do not think a moment that we have here a specific remedy for tubercular disease, but as tannic acid is, even in those large quantities, relatively harmless, and as it seems to me that it regulates digestion and the action of the bowels in an excellent way, and thus benefits the general condition very much, I think it a remedy worth trying in those cases in which we hardly know what to do. Whether it will be of beneficial influence in beginning phthisis I do not know. I only can say that in my cases I could not detect any influence on the bacilli in the sputa.

Urticaria Pigmentosa.—In a monograph on this disease, containing an exhaustive analysis of previously recorded and several new cases, Dr. Raymond discusses a disease of much interest, first studied in England. This affection of early infancy is characterized by urticarial eruptions succeeded by raised or flat patches of a brown color. It has a variable duration, averaging about ten years, and the author thinks it allied to urticaria, but differing very distinctly clinically and in its pathological anatomy. He concludes that it is a special angio-neurosis, marked by a vaso-motor hyperexcitability, and an independent dystrophy or tropho-neurosis of the dermis, ending in the formation of the peculiar cells described as "mastzellen." The peculiar and characteristic coloring of the eruption, which is so interesting a feature, is thought to be due to the accumulation of "mastzellen" and superadded elements, and secondarily to hematin crystals and pigmentation of the lowest cells of the epidermis.—*The Lancet.*

Clinical Department.

CURE OF HERNIA BY INJECTION.

Dr. John G. Harvey, of Blue Mound, Ill., in referring to the recent article by Dr. Dudley P. Allen on the radical cure of hernia, writes: "I wish to add one case operated on by injection as recommended and used by Dr. Joseph H. Warren. On July 16, 1883, I performed the operation by injection, as directed by Dr. Warren, on Mr. Omer C——, aged twenty-two, of good general health. His was an old inguinal hernia on the left side. I used the following formula:

℞. Fl. ext. querci albæ, ℥ vj., reduced by distillation to	℥ ij.
Alcohol, ninety per cent	℥ ss.
Morph. sulph.	gr. iv.
Tr. veratri viridis	ʒ ij.

Of this I injected about thirty minims with a De Garmo syringe. I then applied a rubber bandage with a compress over the inguinal region. I kept patient in bed five days, after which he attended to his business, as salesman in a dry-goods store, as usual. He wore a soft truss for one year, and at the present writing has had no return of the hernia and is in perfect health. The operation was performed without anæsthetics and caused but little pain or after-trouble."

AN UNUSUAL EFFECT FROM THE USE OF COCAINE.

Dr. S. Mitchell, Jr., of Hornellsville, N. Y., writes: "I presume everyone who has used cocaine to any extent has observed some of its toxic effects. The most recent that I have observed, and one that is entirely new to me, occurred in my practice a few days since, in the person of a married lady, thirty-five years of age, of phlegmatic temperament, whom I am treating for deafness, otherwise perfectly healthy. I applied a ten per cent. solution of cocaine to her right nostril by means of pledgets of cotton, preparatory to reducing an hypertrophy of the middle turbinated with the galvano-cautery. In making the application some of the solution passed into the throat and my patient complained of slight nausea. I used the cautery without causing scarcely any pain; but immediately after the operation she complained of a general lassitude both of mind and body, quickly followed by a sensation of numbness in the right arm, then of the right leg and foot, finally of the whole right side of the body except the head and face. There was no feeling of faintness complained of, nor was there any tremor such as I had previously noticed from the toxic effect of cocaine. These disagreeable symptoms all passed away in the course of five minutes, leaving more of an impression on my mind than on that of my patient. I am quite familiar with many of the peculiar symptoms produced by cocaine, due more often, I think, to some idiosyncrasy of the patient than to an overdose of the drug, and which, I have observed, occur more frequently after applying it hypodermically than otherwise. In another case, a young lady, twenty years of age, where I injected ♏ x. of a ten per cent. solution into one of the tonsils, preparatory to excision, she was instantly seized with an uncontrollable tremor of the whole body, accompanied by hurried respiration and faintness. She recovered quickly by the use of stimulants, and I was able to complete the operation without any further bad symptoms whatever."

Meiopragia is the term proposed by M. Potain to indicate the lessened functional power of an organ. The word is derived from two Greek words meaning to diminish and to do, and signifies, literally, lessened efficacy.

Progress of Medical Science.

THE FORMATION AND CLASSIFICATION OF TUMORS.—Dr. W. Roger Williams publishes in *The Lancet*, a review of his views on the formation and classification of neoplasms. He says that the various pathological new formations originate by reversion of cells which are usually engaged in maintaining the normal structure of the body, to an embryonic state of activity. The morbid products, though themselves redundant, generally represent a reduction or *minus* of the corresponding healthy structures whence they originate, differing from them only in degree. In all of these cases, as in the new formations of embryonic life, the subordination of the local processes to the specific hereditary tendency of the whole appears to be lost or diminished, so that unspecialized cells then manifest their potential reproductive qualities by taking on semi-independent growth and development. In short, there is departure from the definite order, limitations, regular stages, and fixed periods of the normal evolution. The classification adopted by the author is the following:

I. *Archiblastic* neoplasms.	1. Lowly organized—	*Epithelioma.*	Squamous. Cylindrical. Glandular.
	2. Highly organized—	*Papilloma.* *Adenoma.* *Cystoma* (neoplastic.)	
II. *Parablastic* neoplasms.	1. Lowly organized—	*Sarcoma.*	Round-celled. Spindle-celled. Myeloid.
		Myxoma.	
	2. Highly organized—	*Fibroma.* *Lipoma.* *Chondroma.* *Osteoma.*	

Many neoplasms are malignant—that is to say, they have the power of reproducing themselves, either locally after removal, or in distant parts; while others have no such infective properties. Need we assume any specific difference between the two kinds of neoplasms to account for this? Certainly not. Between the malignant and the non-malignant growths so many transitional forms exist that it is impossible to sever the chain otherwise than by arbitrary methods, contrary to the nature of things. Upon what, then, does this difference depend? It must be borne in mind that before any neoplastic action can arise in a part, the normal restraining influence exerted by the whole organism upon its cells, in accordance with the specific hereditary tendency of the whole, must be weakened, modified, or withdrawn. Moreover, it has been found that the product of the evolution of cells thus abnormally emancipated varies according as the emancipation is complete or more or less incomplete. The natural tendency of cells thus completely emancipated is to form new individuals by agamogenesis. But in the higher animals this never happens, because the emancipation is always more or less incomplete; hence in them only new parts, new tissues, and neoplasms are formed. Here the nature of the product seems to depend upon the grade of organization attained by the neoplastic cells. It is well known that in the formation of highly organized structures the cells of the part suffer loss or impairment of their proliferous (reproductive) power, owing to their protoplasm being used up and converted into special tissues. Most non-malignant neoplasms are of this nature; their histological character closely resembles that of the corresponding normal tissue, whence they originate. Such neoplasms lack infective properties because they are highly organized. On the other hand, all lowly organized neoplasms are more or less malignant, and the most malignant are the most lowly organized. Hence it may be concluded that the degree of malignancy of a given neoplasm is chiefly dependent upon its grade of organization. To this cause, and not to any essential difference in nature of the morbid process, the author attributes the different behavior of these two kinds of neoplasms.

Viewing the matter in this light, he can see no probability of there being any truth in the theory that neoplasms are the outcome of general *blood* disease, dependent upon the presence of micro-organisms like tubercle and syphilis. He thinks De Morgan came nearer the truth then any one else when, in the memorable debate on cancer at the Pathological Society in 1874, he said "I can see no analogy between new growth, whether as innocent as lipoma or as malignant as cancer, and the products of true general or blood disease in respect to their genesis and destination. From the first a tumor is a living, self-dependent formation, capable of continual growth by virtue of its own power of using the nutritive materials supplied to it. Nothing like this is seen in any of the blood diseases."

EXPERIMENTAL CIRRHOSIS.—Drs. Straus and Blocq have administered to rabbits, by means of the œsophageal tube, alcohol in doses of from eight to ten grammes, increased to fifteen grammes, with three times the amount of water (*The Lancet*). The alcohol consisted of a mixture of ethylic and amylic alcohol. It was found that the administration had to be continued for some months before marked changes in the stomach and liver could be appreciated. In cases where the toxic effects were more rapid acute gastritis occurred; but where the animals survived these early effects the result was a thickening of the mucosa, especially in the cardiac region. The liver did not become notably affected until after seven months, although very slight changes were perceptible at the third month. The changes corresponded to those of cirrhosis in the human subject, consisting in the accumulation of embryonic cells in the portal zones, without, however, any special relation to the bile-ducts or the branches of the portal vein and hepatic artery. The change was rather a diffuse lesion of Glisson's capsule. As a rule, the liver-cells were strongly marked off from the new tissue, but in places the latter had invaded the lobules and isolated liver-cells, suggesting possibility of a primary degeneration of the parenchyma under the action of the alcohol. Even after a year's duration the new tissue showed no signs of fibrous transformation. The distribution of the infiltration suggested that the cirrhosis is at first monolobular, and that the multilobular character held by Charcot to be distinctive of alcoholic cirrhosis is a subsequent development of the process.

CHOLECYSTOTOMY WITH LIGATION OF THE CYSTIC DUCT.—Dr. Zielewicz believes the chief objection to simple cholecystotomy is, that it, as a rule, leaves a persistent fistula and often lessens the nutrition. He says that the "ideal" operation, cholecystotomy with suturing and return of the gall-bladder, has the danger of the rupture of the line of suture due to over-distention of a still partially elastic bladder. Besides this, if new stones form, the operation must be repeated. It seems that cholecystectomy is less dangerous than cholecystotomy. He cites one case in which he made an incision directly over the enlarged gall-bladder and parallel with the median line. A double ligature was passed around the cystic duct and this was cut between the two. The incision was too free and involved the liver substance, causing free hemorrhage, but this was stopped by the use of iodoform and pressure. The bladder was then freed as much as possible from the liver and stitched to the wound in the abdominal wall. Then it was incised and there escaped some bile and a rough mulberry-like calculus of the size of a walnut. The patient recovered. The author claims this as the first successful case of ligature and section of the cystic duct in a human being. The advantages of this method are:

1. Radical cure without a resulting biliary fistula and its consequences. The gall-bladder is excluded from the organism as in exsection. Its secretion, the product of its mucous membrane, diminishes in time because of the

cessation of the biliary flow, and especially after the cavity has become obliterated by newly-formed granulations.

2. The operation is simple and less dangerous than cholecystectomy and gives the same result.—*The American Journal of the Medical Sciences*, August, 1888.

The Delivery of the After-coming Head.—Winckel, at the recent meeting of the German Society for Gynecology, referred to twenty-one methods of extracting the after-coming head. He considered that procedure best which combined pressure externally with the maintenance of the head in that position best suited for birth.

He accomplishes this as follows: The trunk and arms, when born, are raised. Two fingers of the right or left hand toward which the face looks are placed in the child's mouth at the base of the tongue and flexion is secured. The trunk is then placed upon the forearm of this hand and with the other hand pressure is made through the uterus upon the head.

As Wigand and Martin had previously described this method, he styled it by their names. He had found delivery by this method readily effected with a pelvic antero-posterior diameter of two and one-half inches. Martin had employed it successfully in thirty-three cases, and he used it often in his clinic.—*The American Journal of the Medical Sciences*, August, 1888.

Ovarian Tumors in Pregnancy.—At a late meeting of the Harveian Society (*The British Medical Journal*) Dr. Braxton Hicks reported two cases of ovarian tumor, associated with pregnancy, in which the removal of the tumor had been followed by recovery. In the first, labor had continued thirty hours. The tumor came down, and prevented the head being seized with forceps, and turning was tried and found impossible. The child was finally delivered with long forceps, and was still living. The placenta required removal. The tumor grew rapidly after delivery, and was removed. It was adherent everywhere, and was compound in character, nearly colloid. The patient made an excellent recovery. In the second case there was an ovarian tumor which reached rather above the umbilicus. It was diagnosed to be composed of two cysts. The woman had missed two periods, and it was proposed to wait until after the middle of pregnancy. However, the cyst became tense, with pain, and was removed. The pedicle was found twisted, and the tumor adherent and becoming necrosed. No uterine action came on for two weeks, when an ovum was expelled. The cases showed that when ovarian tumor and pregnancy were concurrent, if the tumor gave signs of irritation, the sooner it was removed the better.

Salicylate of Magnesium in the Treatment of Typhoid Fever.—This salt is easily prepared by dissolving salicylic acid in distilled water and saturating the boiling solution with carbonate of magnesium, when crystals of the salt may be obtained in needles, readily soluble in water and alcohol, and both colorless and odorless. Dr. Huchard gives it in doses of from forty to eighty grains daily, and it is not contraindicated by diarrhœa, since it is but slightly laxative even in large doses. It appears to act both as an antipyretic and as an intestinal antiseptic.

The Local Treatment of Diphtheria.—Mr. R. Sanderson read a paper on this subject at a meeting of the Brighton and Sussex Medico-chirurgical Society (*The British Medical Journal*). He argued that, apart from Oertel's elaborate researches, there was sufficient clinical evidence to show that diphtheria was primarily a local disease. The local lesion should be regarded bacteriologically as a "cultivation" upon human mucous membrane; and *cæteris paribus*—that is, assuming a uniform healthiness of organism—the constitutional poisoning was directly proportional to the area occupied by the cultivation. The diphtheritic membranes were a protecting blanket under which and in which this cultivation throve, and, moreover, were in themselves a mechanical danger, and aided the spread of the cultivation by transplantation and continuity. They should, therefore, be thoroughly dissolved early, and redissolved as soon as reformed. He knew of no solvent better than Finkler's papain, and described the method of applying it. Having thus exposed the cultivation, a germicide should be at once used; he preferred acid. carbolic. ʒ j, glycerine, ℥ j. He maintained that by taking a case early and treating the local lesion rationally on the above lines, the area and consequently the toxæmia could be controlled, and the danger of invasion of the nose and larynx minimized.

The Treatment of Chronic Affections of the Heart.—According to Lichtheim, Oertel's method is a sovereign means of cure for those forms of chronic heart disease whose genesis is due to intemperance in eating and drinking, and to lack of bodily exercise. In those diseases of the heart, on the other hand, due to the dilating influences of immoderate bodily exercises, or other causes, this method is of no value. Bodily exertion is only to be allowed in moderation and when there is tolerable compensation, and it must never be allowed to produce much dyspnœa. This class of cases is to be treated much more carefully than are instances of real valvular disease. The treatment with digitalis, strophanthus, and caffeine remains the principal one for disturbances of compensation. Where the use of drugs fails, the dietetic method is also of no avail. Only in the removal of hydrosis is Oertel's method of real assistance to the treatment with drugs, though it can never take the place of the latter. During the period of intact compensation the use of medicaments is superfluous, and Oertel's method, used in moderation, finds its true field.—*The American Journal of the Medical Sciences*, August, 1888.

The Combination of Syphilis with Carcinoma.—At a recent meeting of the Vienna "Medizinisches Doctoren Collegium" Professor Lang showed a case in which syphilis was combined with carcinoma (*Medical Press*). The first cases of this kind had been communicated by Hutchinson and Langenbeck. Lang had hitherto had the opportunity of observing four such cases. The carcinoma which developed later on, on the syphilitic soil, was each time demonstrated by histological examination. In the first case which he had observed, in 1883, there were besides relapses of iritis and other symptoms characteristic of syphilis, also gummatous ulcerations of the face. Under anti-syphilitic treatment all the ulcerations disappeared, except one, which became transformed into a cancroid of the skin. The second case was that of a man, aged forty-six, who had suffered from various syphilitic ulcerations on different parts of the face and the body. After anti-syphilitic treatment one ulcer, viz., that under the tongue, remained behind, and became also transformed into carcinoma. In the third case a syphilitic infiltration of the lower lip relapsed at the end of a year, and assumed a carcinomatous character. The fourth case was now brought forward before the Society. The patient presents several scars on the trunk and the face, as well as perforation of the palate and loss of substance of the upper lip. She had been admitted into the hospital during the month of January. Most of the ulcerations were at that time covered with a white scab, but the histological examination of this substance did not reveal any sign of importance for the diagnosis. Since the 19th of February current, a small ulceration, which was very indolent, became visible over the hard palate. The part which was excised from it for histological examination was found by Professor Weichselbaum to be epithelioma. Professor Lang remarked that these developments of carcinoma on a syphilitic base had not hitherto attracted sufficient attention.

The Treatment of Colic.—Dr. Capitan recommends a pill composed of naphthaline, ½ grain; iodoform, ⅐ grain; tannin and antipyrine, each, 1 grain, for the relief of intestinal colic.—*La Riforma Medica.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published by

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, September 15, 1888.

THE EXTENT TO WHICH LEGISLATION CAN AID MEDICAL EDUCATION.

Mr. W. A. Purrington, the Counsel of New York State and County Medical Societies, read a paper last week before the Health Department of the American Social Science Association, showing the extent to which legislation can go in maintaining a proper standard of medical education. This paper was one of several given before the health department, which had under consideration the necessity of higher requirements for obtaining a medical degree.

Nowhere have the effects of legislation, and its proper limitations, been more ably set forth than in Mr. Purrington's paper. Mr. Purrington sent a circular letter of inquiry to every State and Territory of this country, and also to the British Provinces. Almost every reply expressed approval of some system of regulating by statute the practice of medicine; and the opinion was also strongly given that such legislation as already exists, crude and imperfect though it is, has perceptibly improved the standard of medical education.

Strange to say, there are some opponents to statutory regulation of medical practice who regard it as an infringement of the liberties of the citizen, and therefore unconstitutional; but Mr. Purrington says such legislation is based on principles approved by every judicial authority, and rests on the right of society to self-protection.

The stumbling-blocks in the way of every effort to achieve a wise medical legislation are, first, the ignorance and greed of the believers in, and practisers of, quasi-supernatural methods of treating disease; second, jealousies among the more intelligent adherents to "isms;" third, jealousies between the mother-church of medicine and those of her children that wish to make of their specialties separate professions; fourth, the obstructions from vested interests that consider themselves threatened—the incorporated schools that have some capital invested, and regard their power to confer a diploma operating as a license to practise medicine as their chief stock in trade.

The condition of the statute-books to-day is one of confusion. There are special acts incorporating medical, pharmaceutical, and dental schools, besides acts incorporating medical societies of physicians and of sectarian practitioners of motley nomenclature; general acts regulating the practice of physics and surgery, of dentistry, of pharmacy; and sanitary regulations and laws creating health boards.

Mr. Purrington regards this jumble as in itself an evil, and an efficient cause of the propagation of false ideas. A logical medical law, he says, which of itself will be an educator, will recognize the fundamental principle on which all these statutes are to be defended, that already indicated, the right of the State to protect the health as well as the life and property of the citizen. One health statute will then be enacted and a responsible board created, that will have in charge the arrangements of quarantine and sanitation, and also the licensing of medical practitioners of every sort; for he contends that the dentist and the pharmacist should be recognized as medical men.

He thus sums up what, in his opinion, is all that legislation can do in aid of medical education:

I. By fixing a minimum age under which they (physicians, dentists, and pharmacists) will not be allowed to practise their calling.

II. By requiring of each of them a fixed term of study, of certainly not less than two graded years, leaving to the Board the care of details.

III. By requiring proof by examination or certificate that each candidate for license had studied, before beginning his professional course, at least those branches in which law students are examined in this State before they commence their legal studies.

IV. By declaring that no medical schools (including in the term schools of dentistry, pharmacy, and midwifery) shall be incorporated by special act, and providing a general law for the incorporation of such schools, only upon proof made of the possession by the incorporators of sufficient capital—say not less than a hundred thousand dollars—and a teaching plant, to justify the belief that the school will be capable of exercising faithfully its franchise. Such an act should contain stringent provisions for its own enforcement and for the forfeiture of abused charters.

V. A minimum course of medical study should be prescribed, in which a grade of at least seventy per cent. should be attained on examination. The regulation of all details of the examination should be left to the Board. But the topics in which the examination should be had might well be specified in the statute. It might be well to omit the topics of therapeutics and materia medica, upon which all medical heresies have been begotten by unscientific minds, inferring that one who should creditably pass his examinations in botany, chemistry, physics, anatomy, surgery, physiology, hygiene, diagnosis, obstetrics, and microscopy, especially if his clinical examination should show him to be educated in a true sense to observe and draw sound deductions from observation, might be trusted to form his own conclusions and pursue his own studies as judgment should dictate in the field of therapeutics. The law can have nothing to do with medical theories. The utmost it can do successfully is to prescribe that none shall practise medicine except persons educated in those branches of science that all admit are essential to an understanding of morbid conditions of our species, and possessed besides of a fair general education.

VI. Finally, the law should not recognize any diploma as of itself conferring a right to practise medicine; even if the possession of such document should be required as an antecedent to examination by the Health Board, it should not be allowed to take the place of such an examination. Any scheme of medical legislation will hereafter embrace that great safeguard against imposture and efficient tracer of frauds, the system of registration, where no one is allowed to practise medicine who has not made a public record under oath of his name, origin, and credentials for a license.

THE COMING CONGRESS.

The opening session of the Congress of American Physicians and Surgeons will be held in Washington on Tuesday evening next, September 18th, the opening sessions of the component societies and associations being held on the morning of the same day. Eleven societies are already affiliated to the congress, and two other societies, which have as yet no official relation to the congress, are to meet in Washington at the same time and will doubtless then make application for admission. The societies already represented in the organization are the American Surgical Association, American Association of Genito-urinary Surgeons, American Laryngological Association, American Climatological Association, Association of American Physicians, American Otological Society, American Ophthalmological Society, American Neurological Association, American Dermatological Association, American Physiological Society, and American Orthopedic Association. The two societies which, it is understood, will apply for admission at this meeting are the American Gynecological Society and American Association of Obstetricians and Gynecologists. We really do not see the necessity of two national associations of so similar a character as the last mentioned, and it is to be hoped that some means can be found of uniting them and forming of the two one strong and vigorous society.

The plan of organization of the congress is a novel one in this country, and the wisdom of its originators cannot be presaged with certainty, but must be proven by the result of the meeting. In the case of the American Medical Association, the parent society overshadows, in a measure, the different sections. The latter are subject to the former, and attendance on their meetings varies greatly according to the interest felt in the papers to be presented. The membership is, as it were, a floating one, and each one feels that he is a member of the association rather than of any particular section. In the Congress of American Physicians and Surgeons, on the other hand, the component societies are everything, and the general congress is but a bond of union of an elastic nature, bringing the societies together once in three years and permitting them to meet where they will the other two. Each associate of the congress, therefore, feels a sense of loyalty to his own society, and strives to make its meeting a success, promoting thereby, as it were secondarily, the success of the general congress. It is as an association of federated States, a true democracy, and not as an aggregation of dependencies, the inhabitants of which are loyal subjects of the parent country rather than of the individual colony. The democratic plan is a success politically, and there would seem to be no reason why it should not possess equal advantages in the sphere of science.

But while the tendency of such a plan of organization will doubtless be to stimulate the activity and increase the vigor of each society, there is a possible danger that this may be overdone—that the mass of material presented will be too great for ready assimilation. A too heavy dose of science is like a too hearty meal, it overtaxes the digestive powers, and benumbs rather than stimulates the organism. If the different societies were to meet at different times this possible disadvantage would not exist, and there would be no danger that some really valuable paper embodying original ideas may be overlooked in such a crowd. However, as the congress will meet but once in three years, this disadvantage, if such it should prove to be, will be only an occasional one.

The first general meeting of the congress will be occupied by a discussion on "Intestinal Obstruction in its Medical and Surgical Relations," the debate being opened by Drs. Reginald H. Fitz, of Boston, and Nicholas Senn, of Milwaukee. On the following evening the subject of "Cerebral Localization in its Practical Relations" will be discussed by Drs. Charles K. Mills, of Philadelphia, Roswell Park, of Buffalo, and others. Dr. John S. Billings, the President of the congress, will deliver an address on "Medical Museums" at the closing session.

The meeting promises to be a success, as far as numbers are concerned, and if it is not a success in every other way it will not be through the fault of those who have had the organization of the congress in charge, for their work is deserving of all praise. We sincererely hope that it will be a most successful meeting in every sense, and whether it is or not the readers of THE MEDICAL RECORD will be able to judge from the report which we shall present to them of the work of all the component societies of the congress.

THE YELLOW-FEVER EPIDEMIC.

It is easy to find mistakes after some misfortune has occurred, and the Florida epidemic affords an excellent opportunity to look back and see what might have been done, if only the future had been foreseen.

First of all, the governor, several months ago, refused to call the legislature for the purpose of organizing a State Board of Health, with the especial object of correcting the sanitary imperfections of Jacksonville.

Then, again, we are told that the disease this year originated in a small hamlet called Manatee. There are probably fifteen houses in it. Twenty thousand dollars, or perhaps even $10,000, would have bought all of them and all they contained. If these had been promptly destroyed, possibly the fever would have been checked.

Finally, it seems especially unfortunate that at the outset there should have been so much friction between the Jacksonville people and the Marine Hospital Service. The opinion is that the head of that bureau, though meaning well, was much misunderstood and hampered in his efforts.

CHANGE OF DATE OF MISSISSIPPI VALLEY MEDICAL ASSOCIATION MEETING.—In order to facilitate the most liberal railroad rates, and in keeping with the desire of many important members who wish to be present, the change from September 11th to September 25th has been made by the committee of arrangements and the officers of the cssociation.

News of the Week.

The Mortality from the Yellow Fever at Jacksonville has so far been very light. Up to September 11th the number of cases was 632, and of deaths 78; giving a death-rate of only twelve per cent. In 1878 the death-rate among about 36,000 cases occurring in Louisiana was 16.66 per cent. (Bemiss), and among 800 cases in Charity Hospital was fifty per cent. The most favorable death-rates, however, from this disease run as low as seven to ten per cent.

A Dinner to Distinguished Visitors.—Dr. Fordyce Barker gave a dinner on Tuesday evening, at the University Club, to Sir William MacCormac, Surgeon of St. Thomas' Hospital, London; Mr. Arthur Durham, Surgeon to Guy's Hospital, London; and Mr. Reginald Harrison, Surgeon to the Liverpool Infirmary. There were also present: Dr. William M. Ord, F.R.C.P., physician to St. Thomas' Hospital, London; Professor Horsley, of Cambridge University; Drs. L. A. Sayre, R. F. Weir, W. T. Bull, George A. Peters, and George F. Shrady. Dr Barker welcomed the guests on behalf of the profession of America, which address was feelingly responded to by Mr. Durham, Sir William MacCormac, Mr. Harrison, Dr. Ord, and Professor Horsley. Informal toasts were responded to by Drs. Sayre, Shrady, Weir, Peters, and Bull. The distinguished guests are delegates to the Congress of American Physicians, to be held in Washington the coming week, and cannot fail to add dignity and interest to the proceedings of that body. We can assure them a hearty welcome by the profession throughout the country.

The Coming Congress at Washington.—We shall endeavor in our next issue to give a complete and exhaustive report of the doings of all the sections of the congress to be held next week in Washington. It is to be hoped that the readers of papers will aid our correspondents in promptly obtaining abstracts of papers read and discussed. We shall thus be enabled to publish the entire report in one issue, as has been our plan with other conventions of equal magnitude and importance.

The American Surgical Association.—The following is the programme of the annual meeting to be held in Washington during the coming week: "Excision in Articular Disease," by Dr. John Ashhurst; "The Relation of Micro-organisms to Injuries and Surgical Diseases," by Dr. Nicholas Senn; "Cerebral Localization, the Relation to Operative Surgery," by Dr. Stephen Smith; "Three Cases of Brain Surgery," with presentation of the patients, by Dr. W. W. Keen; "Certain Indications of Trephining, and their Comparative Value," by Dr. J. William White; "The Choice of Operation for Vesical Calculus," by Dr. Hunter McGuire; "Suprapubic Cystotomy," by Dr. John H. Packard; "Forty Years of Chloroform and Ether in Louisville, Ky.," by Dr. D. W. Yandell; "The Surgical Management of Typhlitis and Perityphlitis," by Dr. W. T. Bull; "The Propriety of Surgical Interference in Perforating Typhoid Ulcer," by Dr. J. Ewing Mears; "Report of a Case of Simultaneous Ligation of the Right Carotid and Subclavian Arteries for Aneurism of the Innominate," by Dr. John H. Packard; "Hernia, its Treatment," by Dr. C. H. Mastin; "The Comparative Merits of Tracheotomy and Intubation in the Treatment of Croup," by Dr. George W. Gay; "Pregnancy and Operative Surgery, their Mutual Relations," by Dr. L. McLane Tiffany; "Nerve-stretching," by Dr. N. P. Dandridge; "Nephrectomy for Gunshot Wounds," by Dr. De Forest Willard; "Shock," by Dr. David W. Cheever.

The Programme of the Sixty-first Annual Meeting of the Association of German Naturalists and Physicians has been published. The meeting takes place at Cologne during the week commencing Monday, September 17th. At the general meetings addresses will be delivered by Professors Binswanger (Jena), Weismann (Freiburg), Waldeyer (Berlin), Meynert (Vienna), Exner (Vienna), and Dr. Von Steynen (Düsseldorf). There are thirty sections, including almost every branch of physical and natural science, as well as of medicine. In the Section of General Pathology, papers are promised by Drs. Baumgarten, Benekc, Ribbert, Birch-Hirschfeld, and Anton. Bum; in that of Medicine, by Drs. Naunyn, Leichtenstern, H. Wette, and Ewich; in that of Surgery, by Drs. Witzel, Rosenberger, Tillmanns, and Schimmelbusch; in that of Pædiatrics, by Drs. von Jaksch, Paltauf, and Hagenbach, who take part in a discussion on the Forms of Nephritis following on Acute Infective Diseases; by Drs. Pott and Thomas, on Antipyresis in Infective Diseases; by Drs. Sprengel and Kempermann, on the Operative Treatment of Tubercular Disease of Bones and Joints; by Dr. Unruh, on Post-diphtherial Nervous Diseases; and many other papers. There are also Sections on Gynecology, Neurology, Ophthalmology, Otology, Laryngology, Dermatology and Syphilis, Hygiene, Forensic Medicine, etc.

The Doctors and the Yellow-fever Epidemic.—We take pleasure in quoting the following true and appreciative words from the New York *Sun*: "The whole country has observed with admiration the heroic conduct of the physicians who are battling with the yellow fever in the stricken city of Jacksonville. They have not only remained at the post of duty in the presence of danger, rendering services freely to the needy, but they have striven to surpass each other in deeds of devotion and self-sacrifice. Several of them have fallen victims to the plague during the past two months, and one of the most grievous incidents reported from Jacksonville is the death, on Monday last, of Dr. W. L. Baldwin, who caught the disease from one of his patients in the hospital. Not a few doctors practising in different parts of the country have gone to Jacksonville to render relief to the distressed people, and hundreds of others have nobly offered to follow their example. Truly such physicians are worthy of honor and gratitude from mankind."

The Emperor of Germany.—Dr. Morrell Mackenzie says that Emperor William suffers from chronic strumous otitis media and right hemiatrophy.

Dr. John T. Huddleson died recently in Lancaster, Pa., at the age of eighty-eight years. He was born in Norristown, and studied medicine at the University of Pennsylvania, and was said to have been the oldest living graduate of that institution, though this honor has been claimed for several others.

Mr. Reginald Harrison, of Liverpool, now on a visit, is such an admirer of our country that he is becoming very much Americanized. From a knowledge gained by previous trips throughout the United States, he takes upon himself the responsibility of chaperoning his friends to points of interest. As he expresses it, he boldly inoculates them with the American idea of "length, breadth, and thickness," and has met with most remarkable success. Mr. Durham, of Guy's, is at present a willing patient under his treatment. Both gentlemen are guests of our distinguished townsman, Dr. L. A. Sayre.

The Homœopathic Hospital on Ward's Island is said to be badly managed. There is great difficulty in securing internes, on account of the distance from the city and from the declining belief in the clinical practice of homœopathy pure and simple.

The Mismanaged Morristown Asylum.—Dr. Booth, the conscientious medical director of the mismanaged Morris Plains Insane Hospital, has, after a most crucifying endeavor to right all the wrongs there committed, resigned in despair. The trustees and warden attempted to dictate the treatment of patients. He made a firm protest against the resultant brutality.—*Medical Standard.* Machine politics and local pigheadedness seem to have been at the bottom of the trouble.

Successful Transplantation of Skin from a Leg Amputated Two Hours.—Dr. Stephen Smith, of this city, writes: "You notice the fact in The Record that Dr. Bartens successfully transplanted skin from a corpse, death having occurred twenty minutes before. This incident reminds me that several years since I transplanted seventy-five particles of skin from a leg that had been amputated over two hours, of which number seventy-three lived and grew vigorously."

Removal of a Tuberculous Kidney.—Dr. Mattakouski, of Warsaw, has recently extirpated the right kidney for tuberculosis. The patient had phthisis pulmonalis. She recovered from the operation and was discharged improved.

Vaccinating Against Cholera.—A Russian professor named M. Gamaleia announces his intention to inoculate himself with cholera germs. For some time past he has been experimenting with cholera virus, and he professes to be able to render humanity cholera-proof by "vaccinating" mankind with his attenuated cholera virus. The professor should inoculate himself first and talk afterward.

The Old Story of the Borrower.—A physician residing in New York State writes: "The latest thing out is a man, giving the name of H. Raynor, calls at your office and hands you a card, 'Dr. Lepsie's Improved Combination Microscope, specially adapted for Physicians' Uses. Price, $5.00.' While you are reading the card he goes on to say that he has something here gotten up cheap, especially for physicians' use at the bedside of their patients; something that they can carry in their pockets and use for urinary analysis, etc. In the meantime he takes a prune, or something of the kind that has sugar mites in it, and places some of it on the lens and asks you to look; then a drop of water that has wrigglers in it is given for your inspection. If you hesitate, out comes a 'forty-dollar microscope' of low power, and a drop of the same water is put on and you are asked to compare; with the microscope you see a clear field and only the water and its contents, but with the cheap thing you see all of this, and more too, from the imperfections in the lens. By this time he is in a hurry to take the train or to get to some given point by a certain time, and he has scant time to get there, and he hurriedly makes a sale, or does not."

Doctors will have to stay in their offices continuously if the plaintiff in the following case has any basis for his complaint. We take the account from *The Doctor.* "Theodore P. Jones, of New York, sued Dr. Edward Malone for fifteen thousand dollars damages, claiming that he had neglected his duties as a physician. The case, according to Mr. Jones' story, seems to be about as follows: Dr. Malone, who was attending Mrs. Jones, declared on a certain day that she would probably be delivered of a child before morning. His prediction proved correct, but when Mr. Jones went for the doctor the doctor was not at home. Another doctor was called in. The child was weak and died in a few hours."

An Alleged Solvent for Cataract.—A physician living at Port of Spain writes a letter, published in the *Pharmaceutical Journal*, in which he asserts, from personal experience in his own case, that the juice of a plant called *cineraria maritima* has a curative effect on cataract. His statement is that, in 1868, while in practice at Port of Spain, he began to suffer from impaired vision, which gradually increased. In 1873 he visited Europe for advice, but nothing was done, and he went back. He returned to England in 1878, and a cataract was removed from the left eye by a well-known surgeon, but without any good result. He returned to the colony and had to be led about till February, 1888, when he applied the juice of the above-mentioned plant. He commenced its use on February 7th, and on the fourth day (which the writer is careful to explain was February 11th) he perceived a "faint glimmer of light" in the right eye. After a little while he could with this eye discern figures, and even faces under a favorable light, and tell the time on a white watch-dial. As will be seen, the evidence for the value of the plant is not very strong.

French Justice in a Case of Mistake in Prescription-writing.—A French medical man recently prescribed one gramme of sulphate of atropine instead of a centigramme, the error resulting in the death of his unfortunate patient. The doctor and the chemist who dispensed the prescription have been found guilty of homicide through imprudence, and the former was condemned to pay 600 francs as compensation, and the latter to five days' imprisonment and the payment of 400 francs.

A Case of Yellow Fever in New York.—As we go to press we learn of the death of Professor Proctor, the well-known astronomer, from yellow fever, after an illness of two days. The patient was promptly removed to the Willard Parker Hospital from the Westminster Hotel by Dr. Edson of the Health Board, and the room was properly fumigated. Dr. Conant, the attending physician, recognized the disease in its inception, and the diagnosis was confirmed by Drs. A. Jacobi and Edson. The prompt action of the health authorities in this case shows what can be done in the way of stamping out the disease.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

(Special Report for THE MEDICAL RECORD.)

Fifty-sixth Annual Meeting, held at Glasgow, Scotland, August 7, 8, 9, *and* 10, 1888.

SECTION OF MEDICINE.

WEDNESDAY, AUGUST 8TH—SECOND DAY.

DR. MCCALL ANDERSON delivered the President's address. After thanking the members of the Section for the honor of his election, he proceeded to the consideration of the

DIAGNOSIS AND TREATMENT OF SYPHILITIC DISEASE OF THE NERVOUS SYSTEM.

He quoted from an author in one of the journals, who had said that the majority of cases of syphilis in modern times were mild, and required but little treatment. This he considered as an error, for it was this way of looking upon syphilis as a trifling affair that led to the disease being often almost untreated, whereas, if powerful treatment were used from the first, many patients might be saved from death in after-years from the effects of cerebral disease caused by it. He based what he was about to say upon twenty-four cases which he had collected. When a case of cerebral disease came before the practitioner, he had to make out the diagnosis. This would have to be founded: 1, On the history of the case; 2, on a careful examination of the cutaneous surface of the patient, and on a search for scars or defects in the fauces. Many persons do not like to admit that they have had syphilis, and in many cases they have forgotten all about the early history of the disease, because the infection took place so long ago. Again, cerebral syphilis might be due to hereditary syphilis. In such cases tubercular eruptions or cicatrices had to be sedulously looked for. He had notes of cases where the primary lesion was present thirteen, eighteen, or thirty-five years before the brain disease supervened. In one case of cerebral syphilis, in a man aged forty, he found that the patient had had seven healthy children. He was in a deplorable state, with four sloughing bad sores, when admitted into hospital. He had no history of syphilis, and only presented a rather sallow tinge of countenance to cause a suspicion of the disease. And yet the exhibition of a drachm of mercurous oleate in inunction rapidly restored him to comparative health. Another point in diagnosis was the presence of neuralgia, especially when of an intermittent type, occurring only at night. Sleeplessness was a frequent concomitant of this symptom. Next, the appearance of sallowness was likely to be a possible sign of the disease. The questions of age and sex were all-important. Of twenty-four cases of the disease twenty were men and four women. At or before middle life was the time when syphilitic paralysis most often occurred. Dr. Baffard was right when he said that, excluding a few other causes, syphilis was, at that period of life, by far the commonest cause of hemiplegia. Genuine epilepsy came on in childhood, but syphilitic epilepsy supervened in manhood. Next, the effect of occupation was interesting, and learned persons were said to be more liable to cerebral syphilis than unlearned, yet there was a great deal of syphilitic cerebral disease among the working classes.

A most important point in diagnosis was that various lesions were often combined in syphilitic cerebral cases. Thus one man, aged thirty, had diplopia, epilepsy, and left hemiplegia, and also nocturnal neuralgia. The symptoms in cerebral syphilis were very variable in appearance. Thus a gentleman, in 1886, aged thirty-eight, had first of all slight difficulty in articulating, and numbness of his left foot. Then he could not spell, and became quite aphasic. In this case iodide of potassium did no great good. It appeared that thirteen years previously he had had a hard chancre. He improved greatly under the use of inunction of oleate of mercury. The psychical condition of the patient was an important feature in the diagnosis. The presence of gummy tumors might cause epileptic attacks, and irritability of temper, and insanity might come from occlusion of the arteries. One of the cases was that of a man, aged twenty-nine, who had a dazed and stupid look. He remained unconscious for fifteen minutes on one occasion, and exhibited anæsthesia. There was no history of syphilis, but the inguinal glands were enlarged, and it seemed that four years previously he had had some anomalous symptoms. Mercurial inunction, carried out for thirty days, did this man a great deal of good, and he recovered from the attack. General paralysis of the insane showed, on post-mortem examination, nothing beyond the signs of repeated hyperæmias, and might be caused by syphilis. Where the spinal cord was attacked by syphilis, spinal paralysis ensued.

In 1887 a woman was admitted into hospital who had persistent diarrhœa and retention of urine, which symptoms had lasted for five months. She had constipation, lightning pains, and tenderness over the dorsal vertebræ. There was loss of vision of one eye and the tendon reflexes were abolished. In 1886 girdle sensation was felt as high as the clavicles, and there was almost total anæsthesia. The sexual appetite was absent. Her husband was a soldier, and she had had an abortion soon after her marriage some years before. This patient improved greatly under pot. iod., gr. x., twice daily, and the anæsthesia disappeared. She then was treated with mercury, and was restored to health. The next point in diagnosis was the occurrence of loss of sight or other eye affections. The third and fourth nerves were those most commonly implicated. It had been said that thirty per cent. of all the cases of iritis were syphilitic. The occurrence of minute gummata in the iris was pathognomonic of syphilis. The disease might have a deep hold on the system and cause dimness of the retina or complete destruction of vision. As to the

TREATMENT OF SYPHILIS,

whenever doubt was possible the patient should get the benefit, and be treated with specifics. Of course, even then the treatment may do no good, as it might be far too late to be of service. In all suspicious cases, mercury should at once be administered. Iodide of potassium was sometimes of great service, given in very large doses, *i.e.*, as much as a drachm when necessary. The subcutaneous injection of a weak solution of corrosive sublimate was often a useful way of giving mercury. Mercurous oleate was an excellent remedy, although a little dirty. When mercury was injected, it was as well to freeze the skin first and inject a little morphine before the mercury. The mercurous oleate was best prepared without heat. This plan often removed syphilitic skin diseases with great rapidity. Finally, cases of locomotor ataxia were sometimes syphilitic and curable by mercury. A gentleman, aged forty-three, in 1885 suffered from this disease arising from syphilis, and had been rapidly cured by inunction.

DR. DRUMMOND said he had made a considerable number of post-mortem examinations of patients who had died of the effects of

CEREBRAL SYPHILIS,

and had met with meningeal cloudiness at the base of the brain, with various vascular lesions. There was a peculiar variety of arteritis, the nodular, which he had noticed occasionally; this lesion affected also the retina. Gummatous affections of the pia mater might occlude the vessels. He thought that perhaps the most common affections were gummy tumors of the brain, with super added meningeal inflammation. Insomnia and headache at night were frequently symptoms accompanying cerebral syphilis; but it was too frequently assumed that headache must accompany cerebral syphilis. This was not so. In some cases headache was produced; in others, that symptom was entirely absent. There was often no history of syphilis in cases in which the disease had evidently been the cause of the cerebral symptoms. A gentleman, aged thirty-seven, suffered severely from neuralgia, but was in other respects in very good health. Suddenly he became aphasic, and lost consciousness. He soon after had right hemiplegia, with complete aphasia. There was, however, some mention of the patient having suffered five years before from neuralgia of the fifth pair of nerves. With respect to treatment, mercury and iodide of potassium together were often required.

Dr. Grainger Stewart introduced a patient, a woman, aged fifty-eight, who had suffered for fifteen years past with

A SINGULAR AFFECTION.

There was no avowed history of syphilis, but she said that she had once suffered from rheumatic fever which had lasted for six months, and from ptosis and from polyuria, with fits of giddiness and transient paralysis. These were all probably syphilitic. She had at present good health in other respects, and there were no other nervous symptoms beyond the following very remarkable one, which was that, being blind in one eye, as soon as she closed the other eye she at once became unconscious; her head fell, and she had stertorous breathing. There was limited field of vision in the eye that retained some power of sight. She had been blind in the right eye for sixteen years, and posterior staphyloma was seen, with paralysis of the motores oculi of that eye. Even the shutting off of the sight of surrounding objects, by bringing a piece of paper near the eye, produced this curious symptom. When in this unconscious condition she could be pricked with a pin without feeling the prick. Even pulling down the blinds of the room would set her off. She was forced to go to bed with a candle burning, otherwise she would fall down and injure herself if the light was extinguished as she walked toward the bed. Dr. Stewart had watched the case for sixteen years, and during all that time she had never had any epileptic seizure, and no other illness of a nervous kind except the one described. He feared that a scar was present on some part of the brain, for no remedies had any power in removing the symptom.

Dr. Ross, of Manchester, characterized this as a most unique and puzzling case. It was not hemiopia. In one case of cerebral syphilis seen by him, polyuria was a symptom in company with paralysis of the motor oculi muscles of one eye.

DISEASE OF THE PITUITARY BODY

situated below the optic commissure might produce such symptoms. With regard to the diagnostic value of headache, much caution was needed in explaining this symptom. It was often due to cerebral syphilis; but that disease often exhibited no symptom of the kind. A patient of his had severe pain in the head at Christmas, and three months subsequently syphilitic paraplegia, which was followed by right hemiplegia and aphasia. He had then an attack of melancholia. The early symptoms had occurred fifteen years previously. Dr. Ross then sketched the different nerve-centres of the brain, and gave his hypothesis as to the way in which syphilis gradually invaded one of these after the other. In many instances syphilis of the cortex extended along the vessels until it reached the fissure of Sylvius and the centres of speech. Thus facial paralysis was sometimes the initial symptom, and this was followed by motor oculi paralysis. In the syphilitic affections of the cord the disease often commenced in the region of the lower dorsal or lumbar vertebræ and was followed by paralysis of the sphincters and loss of sexual appetite, with incontinence of urine and abolition of tendon reflex.

Dr. Clouston, of Edinburgh, spoke of

THE MENTAL RELATIONS OF CEREBRAL SYPHILIS.

He said that the most melancholy effect of syphilis was that it sometimes produced acute delirium during the secondary period. This resembled delirium tremens. The patient might die in fourteen days, after suffering from great mental irritability throughout the case and maniacal symptoms. Such cases were absolutely intractable. There was also brain-softening, independent of vascular lesions. The third form of cerebral syphilis was the commonest, and that was slow arteritis, which caused gradual starvation of a part of the brain. In such cases there might be no paralysis and no anæsthesia. Such patients began first to exhibit a want of moral feeling and impetuosity, with suspicious delusions and dementia gradually supervening. There was no headache at the commencement, but gradual starvation of the intellect. Lastly, there were the gross forms of disease of the brain which caused mental alterations. He asked the question whether syphilis could attack the neural tissue. It had been said by Dr. Hughlings Jackson that it could not, but the speaker was not quite sure of this, and thought that in some cases that tissue was affected by the disease.

Dr. Robertson thought that there was no disease of the brain caused by syphilis corresponding with that which caused locomotor ataxia. He adverted to the difficulty which was often experienced in making out that a patient had suffered from early syphilis while he was presenting the symptoms of cerebral syphilis, and he mentioned the case of one patient who strenuously denied any infection of the kind, but on whose penis there was a large scar. Syphilis was especially a disease of the cortex, and therefore, in many instances, pain could be made a prominent symptom if only the patient's head were percussed. On doing so over a spot where there was some syphilitic inflammation, the patient would suddenly exclaim that he felt a dull pain over a circumscribed spot. With regard to treatment, all were now agreed that the use of both mercury and iodide of potassium was indicated in cerebral syphilis; but there was a point that was not often insisted on, and that was as to the value of local blistering in such cases. This was often of very great service indeed, where there was cortical inflammation, and in cases of cerebral syphilis, and also in cases of locomotor ataxia, percussion should be carefully used to map out the spot where the inflammation existed, and that spot should be frequently blistered. This relieved pain in a marvellous way.

Dr. C. R. Drysdale said that the abuse of tobacco and alcohol seemed to him to increase the liability to cerebral lesions in those suffering from syphilis. Sclerosis and gummy deposits were what constituted the lesions in cerebral syphilis, whether affecting the dura mater, the pia mater, or the vessels of the brain. The lesions were usually seen at the periphery rather than at the centre of the brain. The sphenoidal region is most often affected with encephalitis or softening of the brain. The prognosis is grave, because treatment is often begun too late, but some cases are permanently cured by energetic treatment.

Dr. Coghill mentioned a case in which a man suffering from cerebral syphilis was covered with rupia. He was aphasic. This gentleman was supposed to be one of those who were intolerant of iodide of potassium; but on putting him on large doses this was found to be a mistake. Thus for eighteen days he took about six drachms daily of the drug, and this had a marvellously curative effect on his case.

Dr. Byrom Bramwell said it was rare to find gummata in the occipital lobes. Multiplicity of the lesions was of great assistance in making out the diagnosis of the disease, and the age of the patient and male sex were of service also. While it might be true that intellectual work might make the rich more liable to get cerebral syphilis, the poor were more subject to blows on the head and were often affected.

Dr. Dowse, of London, said that syphilis was a very different affair now from what it used to be thought to be twenty years ago. The vaso-motor system of nerves was often affected in syphilis. Dr. Jackson, indeed, spoke of the vessels being first attacked; but it must be remembered that these were under the influence of the organic system of nerves.

Dr. Andrew Smart read a paper on

SOME FORMS OF UNDESCRIBED RESPIRATOY NEUROSES.

This paper was illustrated by a number of diagrams. He cited cases of patients who had exhibited as many as one hundred and fifty respiratory efforts per minute, and two hundred and fifty pulsations of the heart. These symptoms were probably due to vaso-motor spasm.

Dr. R. L. Bowles read a paper entitled

AN INVESTIGATION AS TO THE CAUSES OF STERTOR IN ANIMALS.

He said that the expression "snoring like a pig" was clearly illustrated in the Smithfield Club Cattle Show, where the herbivorous animals, however fat they might be, had no stertor, while the carnivorous pigs were types of stertorous animals. This was due to the peculiarity of the gullet and windpipe in carnivora.

Dr. Drysdale read a paper on

ALCOHOL AS A THERAPEUTIC AGENT.

He said that at the present time, in London hospital practice, a much smaller amount of alcohol was prescribed than formerly. Patients had no doubt often succumbed to overdoses of brandy or wine in acute bronchitis, pneumonia, and fevers. As a rule, patients with typhoid fever did better without alcohol, and children should very rarely indeed take alcohol when they were suffering from febrile diseases. In cases of shock alcohol was sometimes of great service. In fevers, when it was thought best to give alcohol, it should be administered in the form of rectified spirits suitably flavored by the prescriber. The author said that of late years he had been giving less and less alcohol, as he had found other remedies much more useful.

The following papers were also read: Drs. Byrom Bramwell and Milne Murray gave a demonstration of the methods of graphically recording the exact relations of cardiac sounds and murmurs; Dr. Maclachlan showed a patient suffering from Addison's disease; Dr. John Shaehan read a paper "On a Case of Pernicious Anæmia successfully Treated by Arsenic;" Dr. Affleck narrated two cases of Raynaud's disease (symmetrical gangrene); Dr. A. J. Harrison sent a communication "On Further Researches on the Treatment of Tinea Tonsurans." This paper was illustrated by photographs. Dr. Thomas Oliver read a paper "On Clinical and Pathological Bearings of Malformations of the Heart as seen in Patent Foramen Ovale and in Imperfect Ventricular Septum;" Dr. Orlando Jones read a paper "On a New Remedy for some Forms of Heart Disease." Dr. Handford read a communication "On the Condition of the Heart in Chlorosis;" Dr. David Finlay read a paper "On Bronchiectasis Treated by Incision and Drainage," and Dr. S. Coupland communicated a case of subphrenic abscess.

Dr. Theodore Williams read a paper on

THE VALUE OF INHALATION IN LUNG DISEASE.

He said the question was whether our present methods of inhalation reach the different parts of the lungs as well as through the stomach. That substances could be thoroughly inhaled was proved by the fact that the nicotine of tobacco had been found in the urine. Warm, moist inhalations had not been successful in his own cases. The reason appeared to be that the air-passages are not adapted to absorb large portions of water even in the form of vapor. Another reason was the patient's inability to make deep respiratory movements, which would make it possible for the air to reach the alveoli. In regard to antiseptic respirators his experience had not been fortunate. Medicinal inhalations were most useful in the larger bronchi.

Dr. Andrew Smart exhibited some specimens of new respirators. He also explained the action of a new instrument for needle puncture.

Dr. Lindsay said his conclusions closely agreed with those of Dr. Williams. Inhalations were very valuable in diseased conditions of the pharynx and the larynx, but very uncertain in affections of the lungs proper. He had tried steam without being favorably impressed by its effects. Persons who had been steamed generally remained susceptible to colds; but the real controversy on the subject of inhalation ranged around phthisis. His results had been altogether negative. He had seen nothing hitherto to show that drugs so given could affect the seat of the disease. It was very doubtful whether they could destroy bacilli, and if they could it was a question whether they would do much good. Our treatment should be rather to decrease the receptivity and leave the bacilli alone. In phthisis the best method, to his mind, was to improve the general conditions by an improved mode of life, by diet, etc., and in proper cases by judicious changes of climate.

Dr. Ireland said he had begun to study the question of inhalation. It was a popular belief in Germany and other parts, where there were extensive pine forests, that the breathing of the air permeated with the odor of the pine was good for lung diseases. It was believed, moreover, that those who lived in the pine forests were singularly free from chest diseases.

Dr. Coghill had not found his expectations always realized in regard to inhalation. But, although he had not yet been successful, he was more convinced than ever that inhalation would yet play a very important part in the treatment of lung disease. Not the least of its advantages was the increase it gave to the respiratory act, the larger amount of air brought into the lungs, and the expectoration was got rid of with greater facility. There were great differences of opinion in regard to the various methods of inhalation. His opinion was that the oronasal method was not the best.

Dr. Smith referred to cases, not frequent in this country, of

HEPATIC ABSCESS BURSTING THROUGH THE LUNG.

Many cases came to England from tropical countries, and in such cases he had obtained very great benefit from antiseptic inhalation. The effect had been to decrease the discomfort of the patient and to diminish hectic. There was a prevalent error that phthisical cases ought to escape from England. Such cases sent to India during the tropical rains ran a rapid course. To send such cases to India was one of the most fatal mistakes of practical medicine.

Dr. Dennison, of Denver, Col., said he thought it was impossible for the medicated air to get to the point desired. The inhalations went to the healthy lung, and not to the diseased one. The chief benefit of inhalation, to his mind, arose from the breathing of more air. The bacilli could not live in a dry climate like that of Colorado, and the important thing was to get the bacilli into such a climate.

Dr. Gibson recommended dry powder inhalation, and said important results were obtained by this method. In this way a great variety of drugs could be employed in the most efficient manner.

Dr. Brett spoke of the necessity of getting the bad air out of the lungs. He exhibited a whistle which a phthisical patient had been recommended to use, and he was of opinion that it might be useful in making the patient respire. He quoted the remark of an old physician, that "not nearly so many persons would die if they would only expire."

Dr. Williams thought the discussion confirmed his general conclusions. There was a good deal of evidence in favor of inhalation. He had found dry powder inhalation of great service in laryngeal affections; but he doubted whether they went further.

Dr. Caverhill showed a patient exhibiting remarkable symptoms connected with

DISEASE IN THE MOTOR AREA OF THE BRAIN.

The patient was a boy, who, when touched on the head, dropped to the floor. He said an account of this case appeared in the *British Medical Journal* of November 20, 1886. Some new developments, however, had appeared since the case was reported. He had had epileptic fits. The curious thing in reference to the malady was the force with which he seemed to be drawn down when touched. On one occasion a window-curtain touched him on the back of the head, and he at once fell on the window-sill. He fell with such force that one of his front teeth was embedded in the wood of the sill, and it took some force to pull the tooth out. The malady dated from his second year, when, as his nurse was carrying him to the bath with some hot water in her hand, she let him slip. She said he did not touch the ground; but it was possible that she was mistaken in that; another circumstance was that after the accident he had had a dread of running water. There was a sound of water running into the bath at the time.

Dr. Jackson, who had formerly had the boy under his care, said that at one time a change took place. He commenced to have epileptic fits, and while he was subject to them a touch on the head produced no effect.

Dr. Pavy read a paper on

NEUROTIC SYMPTOMS IN ASSOCIATION WITH DIABETES.

He said he had referred to these symptoms at the Cardiff meeting of the Association. He found these symptoms accompanied by disordered nerve-action; they caused great pain, and were often referred to neuralgia. They were also referred to rheumatism and sometimes to gout. Referring to the symptoms of an ataxic patient, he said he was perfectly satisfied that certain symptoms of nerve-action, especially connected with the spine, were very apt to occur in diabetes. He had, for some time past, been led to consider that there was some connection between the two. They sometimes came on together, and sometimes the ataxy came on with the diabetes. Not infrequently there was deep-seated pain. Those pains were generally worse at night. He was inclined to look upon these different symptoms as referable to the condition of the spinal cord. He had found it associated with the milder form of diabetes after the middle period of life. It was really surprising how many persons beyond the middle period were found suffering from these conditions. It was of great service to physicians to be acquainted with the conditions they were likely to come across, because it gave them evidence by which they could recognize the precise nature of what was to be dealt with. He had not found a single case that had resisted iodide of potassium.

Professor Jacobi recommended the use of iodide of sodium as preferable.

Dr. Smart said he had never found this nervous condition supervene until the disease had reached a very acute state menacing life.

Dr. Harrison referred to a case in which the developments resembled those of angina pectoris. There was considerable irritation about the heart. Examination of the urine showed traces of sugar.

Dr. Ross agreed with Dr. Pavy in thinking that these sensory phenomena were met with chiefly after the middle period of life. He thought there was a gouty element. But the reflex was frequent in young people. ometimes the gout was somewhat ataxic. In the after-eriod the sensory affections were very prominent. He had seen one or two cases in which the phenomena were very marked.

Dr. Stacey Wilson read a paper on the

METHODS OF DILUTING THE BLOOD AND THEIR CLINICAL USES.

He described the various methods of injection employed, and recommended as of particular value the method which he had employed, of injection into the muscular tissue of the shoulder. He injected half a pint of normal saline solution. The effect was most marked. The patient vomited freely for a time. Vomiting returned the next day. Another pint was injected. After that recovery was steady, and after a few days all urgent symptoms had disappeared. The injections were made by means of the hypodermic needle. Normal saline solution was all that was needed. Carbonate of soda was sometimes used, but it was painful, whereas the saline solution was not. The injections could be made into one shoulder in the morning and in the other in the afternoon.

Dr. Tomory read a paper on

EAST AFRICAN FEVER,

with special reference to climatic conditions.

SECTION ON SURGERY.

Wednesday, August 8th—Second Day.

Professor George Buchanan delivered the

PRESIDENT'S ADDRESS.

He said that he was the first person in Glasgow to adopt the practice of pure surgery, which he did upon his return from the Crimea. He was joined soon after by Sir Joseph Lister, and Sir G. Macleod followed later. He mentioned. also, that he was the first person in Scotland to be anæsthetized.

The discovery of recent times, which perhaps had caused the greatest interest, was that of the tubercle bacillus, not only because it showed that tubercles was, what it had long been suspected to be, a germ-produced disease; but because it gave hopes that many other similar diseases, such as syphilis, cancer, etc., might also be proved to be bacillar in their causation. It must be remembered that a microbe could live only in a suitable constitution, so that it must be looked on merely as the exciting cause of tuberculosis, cancer, etc. Still, there was a newly discovered error in the environment which would have to be taken account of in hygiene as well as in therapeutics. Operations on the head, chest, and abdomen were now practised daily, which a few years ago would have been considered to be quite unjustifiable; indeed in some, if he might be allowed to express his opinion in that chair, the limit of justifiability had been overpassed.

Mr. T. Pridgen Teale, of Leeds, opened the discussion on

THE SURGICAL TREATMENT OF ABSCESS OF THE LUNG AND OF EMPYEMA.

Within the last few years pulmonary surgery had come to the front. His attention had been specially called to the subject by four cases of suppuration under his care, of which two recovered and two died. In two other cases where suppuration was suspected, he explored freely but without success. Both patients died in a few days, unrelieved. The principal points were as follows: Case I. was reported in the *Lancet* of July, 1884. The patient had pain about the colon, with transient obstruction of the bowels. After the lapse of some months dulness was discovered on the right side of the thorax. He tapped it, and brought away a few drachms of clear fluid. He then introduced the trocar, and this time drew a pint of thin stinking pus. The patient was much relieved, but the dulness returned. He ought not to have taken it for an empyema, but for abscess of the lung, because there was such a difficulty in withdrawing it. He opened up and drained, and the man ultimately made a good recovery. Case II. was diagnosed as abscess of the lung. He found dulness at the lower part of the right side of the chest behind, so he put the patient under ether and inserted a trocar in the posterior border of the axillary line, and a pint of clear fluid was drawn off. As there was still much dulness about the right axillary border, a trocar was introduced, and a pint of pus withdrawn. The trocar passed through the diaphragm into an abscess-cavity situated above the liver. He enlarged the opening through the diaphragm and introduced a drainage-tube. After a period of anxiety, the patient began to rally, and in three months was well enough to address an assembly of more than three thousand persons. So much for the successful cases. In Case III. he found a cavity of the liver, from which he withdrew three and one-half pints of sweet pus. There was an opening through the diaphragm into the base of the pleural cavity. For a week the man did well. Then hectic symptoms set in, and six weeks later he made another opening, between the eighth and ninth ribs, and found a large abscess-cavity connected with the other. The patient died a fortnight later. In the fourth case, notwithstanding a large excision, the patient died in a week. The abscess was found to have burrowed behind the liver and the posterior mediastinum, so that recovery was out of the question. Two other cases had been mentioned to him, one a female dispenary patient, who had suffered from pleuro-pneumonia, with pain and dulness at the base of the right lung, and expectoration of offensive pus. Puncture brought away about an ounce of serum, and a diagnosis was made of abscess of the lung. Puncture in front of the angle of the seventh and eighth ribs, with excision, gave exit to forty ounces of fetid pus, and the patient made a slow but uninterrupted recovery. The last case was that of a farmer, aged forty-one, who had had pneumonia on the left side, and who began to spit pus the next winter.

Then the right lung became bad, and the expectoration of pus became profuse. In March, 1888, he became worse and appeared to be sinking. His chest was then tapped, letting out a quart of pus. He was now comparatively well.

Surgeons were losing their fear of exposing the pleura and the lung, just as they had learned how to deal boldly and safely with the peritoneum. In cases in which the mechanical difficulty threatened the life or impeded the recovery of the patient, the surgeon must decide as to the best means of shutting off air to the wound, while allowing of drainage. The region of the diaphragm was a region in which abscess amenable to surgical treatment often occurred, tending to discharge through the diaphragm or lungs. This kind of abscess might be more satisfactorily attacked through the thorax than through the abdominal wall. The cavity might be irrigated by an antiseptic wash during the early periods, until the pus became sweet, but not afterward. With regard to the question of excising a piece of the rib, the tendency was to reserve it for special cases rather than to make it a general rule of practice.

Sir Spencer Wells related a case in which he had been enabled to observe the effects of

DRAINAGE OF THE PULMONARY CAVITY

after forty years. The patient was an invalid seaman who had long presented symptoms of phthisis. An abscess formed in the right axilla, which was taken for a suppurating gland. It was soon found, however, that the abscess communicated with the bronchial tubes. The case was left entirely to nature, and the man recovered, and when he heard of him a few days since, quite accidentally, he was still strong and well.

Dr. Ward Cousins said a few words, bearing on the simplest forms of operation and the simplest way of performing them. Every case of empyema should be considered by itself and treated accordingly. He had given up aspiration and the use of small drainage-tubes. Most of his cases were young children. He showed a trocar which could be converted into a knife, thus enabling him to cut from within outward. He never used drainage-tubes after the first week or two. In most cases of obstruction to the exit of pus the obstacle was at the orifice, and it was far more comfortable to the patient to dilate than to use a drainage-tube. He was strongly in favor of making several incisions, but did not resort to irrigation. He mentioned cases in which the most distressing symptoms were promptly relieved by incision, even when a fatal result was not averted. He said that the lung might be dilated by properly directed gymnastic exercises, and the tendency to deformity thereby obviated.

Dr. Jessop said the first thing was to observe the presence or absence of pus, and when present, no matter where it was situated, it became their duty to evacuate it. He mentioned a case of carcinoma in the axilla in which he accidentally opened the pleural cavity in two places, but no ill effects followed. The patient left the hospital within a month, none the worse for the pleura having been opened. The last case was one in which he removed a large enchondroma from beneath the left breast of a woman. He found it necessary to remove a portion of the subjacent rib, in doing which he opened the pleural cavity; he found that very little impression had been made upon the lung. He therefore only drained and, so far, the result had been quite satisfactory.

Dr. Duncan said they were all agreed that whenever matter was formed within the thoracic cavity their duty was to evacuate it, but the means to be adopted to bring about the closure of the cavity varied very much according to the case. Adult cases, however, were very different. If asepsis were only maintained, simple drainage proved very satisfactory. There were, however, one or two points connected with drainage which had to be attended to. Only a small portion of the rib should be excised, otherwise the ribs fell together, drainage was interfered with, and pain was caused. Another important point was not to insert the drainage-tube too low down—not close to the diaphragm, for instance. With these precautions most cases, whether of abscess of the lung or of empyema, will terminate favorably. He showed an apparatus which he employed for continuous aspiration. Another class of cases was those in which the empyema had lasted for a very long time, in which the patient was likely to die of amyloid degeneration. In such cases excision of large portions of the thoracic wall had proved very beneficial, and he had obtained great success in four out of nine cases.

Dr. Webb observed that

BOTTLED-UP PUS WAS AS MISCHIEVOUS AS BOTTLED-UP SEWAGE,

and treatment must be directed to letting it out. He believed in free incision and used antiseptics. He mentioned a case in which several free incisions were made and several pints of stinking pus removed. The patient had done well, and now there was very little discharge. There was no longer any dulness, and vocal fremitus was restored. He remarked that carbolic acid, when injected into the pleural cavity, often gave rise to a distinct and disagreeable taste. He had never seen any untoward result follow the opening of the pleura, though he had often seen considerable damage follow unnecessary delay.

Dr. Griffiths, of Leeds, mentioned

A SERIES OF CASES OF EMPYEMA

admitted to the Leeds Infirmary, where they had had no less than fifty consecutive cases, varying in age from one year to fifty-six. He did not approve of excision of the rib unless especially called for. Failure of drainage never resulted from non-excision, and he did not believe the pressure of the ribs upon the drainage-tubes actually took place. He alluded to the various explanations as to how the empyemic cavity filled up, and quoted Dr. Samuel West's experiments to show the tendency of membranous surfaces to adhere together.

Dr. Wakefield, of Oxford, mentioned a case of empyema in which the tube had slipped back into the pleural cavity and the wound had to be enlarged later on in order to get it out. He said that in future cases he should be disposed to remove portions of the ribs, at any rate in adults.

Mr. E. Owen could not see any objection to removing a portion of the rib, and he asked what harm could it do. He indicated a method of avoiding the danger of the tube slipping back by fixing it to a shield. He avoided irrigation unless it were found to be absolutely necessary. He mentioned a case of hydatid cyst pushing up the diaphragm, which he had attacked through the thoracic walls and in which the healthy pleura showed no tendency to irritation.

Dr. Lloyd asked how they were to distinguish between circumscribed abscess of the pleura and abscess of the lung. He thought Mr. Teale's instrument subjected the patient to the risk of diverting a purulent collection into the healthy pleura. He suggested that it was possible to make a large opening without removing a portion of the rib by running the knife along the ribs.

Mr. Teale, in reply, said the point had been established that they need have no fear of opening the pleural cavity even when healthy. This facilitated their action in doubtful cases. He questioned the accuracy of the belief that the lungs would collapse if air was admitted. This belief was based on what occurred in pneumothorax; but the case was quite different. He regretted he could give no more assistance in differential diagnosis. He called attention to two points as rather indicative of abscess of the lung: First, the expectoration of stinking pus; and second, when, on exploring the pleural cavity, they got a clear fluid without pus, showing that the pleura was irritated by the presence of a contiguous abscess in the lung-tissue itself.

Dr. Th. de Valcourt read a paper on

WINTER SEA-BATHS AT CANNES,

in cases of scrofulous disease.

Dr. Murphy, of Sunderland, showed a patient on whom he had performed

GASTROSTOMY

eleven months previously. The patient, a man, forty-seven years of age, had gradually become unable to swallow in consequence of a constriction (cancerous?) of the œsophagus. The man had recovered from the operation without a bad symptom, and now fed himself regularly through the artificial opening. He had gained over twenty pounds in weight. He was still quite unable to swallow even a few drops of milk, but his general health was good. He had no perception of taste when food was passed into the stomach, but he could detect differences of temperature. Dr. Murphy expressed the hope that the suspicion which attached to the operation would be dissipated when it was shown that good results might be obtained, if the operation were not deferred until the vital powers were at too low an ebb.

Dr. Carmichael read the notes of a case of gastrostomy in a woman with stricture of the œsophagus. The difficulty was less in the operation itself than subsequently in preventing leakage of the stomach-contents. This was ultimately attained by means of a tampon of hour-glass form, which could be inflated *in situ*. The patient left the hospital in fairly good health, but died from pneumonia one hundred and two days after the operation. At the autopsy they found a cancerous mass involving the gullet below the thyroid gland.

Mr. Benton read a paper on

THE TREATMENT OF STRICTURE OF THE RECTUM BY ELECTROLYSIS.

He mentioned a number of cases in which the stricture had yielded after a single application and in which the benefit obtained had been permanent. He generally used a twenty-cell battery, each séance lasting about ten minutes, with a fortnight's interval between the séances. The strength of the current was about fifteen milliampères.

Dr. Duncan read a paper on the value of

ELECTROLYSIS IN ANGIOMA AND GOITRE.

He had used it in large port-wine stains, nævi, cavernous angiomata, cirsoid aneurisms, etc., in nearly all of which he obtained excellent and perfect results without any untoward symptoms. He claimed that electricity was the best method of treatment (1) when the growth was extending; (2) when it was desired to avoid scarring; and (3) when the subcutaneous tissue was extensively involved. He had treated eleven cases of cirsoid aneurism with success, and he said this was the only justifiable treatment for that affection. He used a current of from forty to eighty milliampères, but no galvanometer was required where the strength and duration of the current were determined by the effects produced. The negative pole was the more energetic, and should be freely moved about.

Dr. Beaven Rake, of Trinidad, discussed the value of

NERVE-STRETCHING IN LEPROSY,

to combat the nervous phenomena in that disease. He had performed the operation one hundred times on sixty patients. It occasionally produced a good effect in checking ulceration, and relieved pain, but it did not seem to do any good in cases of anæsthesic leprosy. Stretching of the sciatic nerve was the most satisfactory, and that of the median nerve came next.

Sir Andrew Clark was to have read a paper on a case of

CATHETER FEVER,

but he preferred, in place of giving his paper, to describe the case *viva voce*, in order to make it briefer. He said the case he was about to relate was one which was under the care of Mr. George Pollock and Mr. Howe. The subject of catheter fever had been discussed at most societies, but it must be confessed that we remained as yet ignorant of its exact nature and also of its true causation. The patient had been practising as a dentist in London, and, after retiring from active practice, he noticed that he was suffering from irritability of the bladder. The urine had its full percentage of urea, and contained a slight excess of muriatic acid. He was quite healthy, although disposed to gout. Impatient of his irritable bladder, he decided to introduce a catheter, and secured a new red-rubber catheter. He oiled it very freely with a little clock oil of unknown age before introducing it, and when he introduced it he removed an ounce of healthy urine. He felt quite well all the rest of the day, but the next morning he told his wife he felt as if he were going to be ill; and so much did this feeling of malaise grow upon him that he kept his bed. In the afternoon of March 29th, eighteen or nineteen hours after the introduction of the catheter, he had a most violent rigor, lasting two hours. During its persistence the temperature rose to 105° F., and the pulse to 116, and respiration became oppressed. The patient took an opiate with a diaphoretic, but passed a very restless night. In the morning he felt very ill, and his friends sent for Mr. Pollock and Mr. Howe, who found him in an advanced stage of catheter fever. He was very thirsty, and had a frequent desire to pass water, which, when passed, was discovered to be clear, but containing albumin. His heart was acting violently; he had slight headache with some confusion of mind. During the day these symptoms abated a little. In the afternoon he had a second and last rigor. The temperature rose to 105° F., and afterward his condition was one which caused great alarm to his physicians. On the third day the typhoid state continued. The bladder was extremely irritable, the urine had been smoky, and contained over thirty per cent. of albumin. It was found to contain epithelial casts, with much blood and pus. Up to this time there were no bacteria in the urine. He was then ordered small doses of quinine, and it was directed that from time to time, while the condition of the pulse continued, he was to have five drops of aconite. While pursuing that treatment he began to get better, and next day there were signs of this symptom passing away. But the local symptoms continued. He had frequent passing of urine, which now, for the first time, contained bacteria. The typhoid state continued, and finally retention of urine occurred. Then the medical men introduced the catheter for the first time, and drew away a pint of blood and urine, which contained multitudes of bacteria. Next day the patient was much better, the constitutional symptoms now subsided, the tongue was clean, and the bowels were opened. From this time to the 28th of April he was getting well. He had a frequent desire to pass water, and the catheter was introduced twice a day. But on this, the twenty-ninth day, the patient became impatient, and under the affectionate interest of his wife he began to take solid food and left his room. Next day he was very ill. The fever returned, and the loathing for food was as great as before; the local symptoms were aggravated. He was put to bed and diaphoretics were given. Under this treatment he was well again in three days. He remained well until the 26th of May. Again the same thing happened; he returned to solid food and left his room, and in the early days of June he was attacked with febrile symptoms, and once more he had to be put to bed. In three or four days he was quite well, and so he remained up to within a few days ago. Then he emerged from an illness from which none of them believed he would recover, but there remained three defects. In the first place, he was a little weak; in the second, he had a mild vesical catarrh; and in the third, there is a slight kidney affection. The actual mass of urea is less than a man of his bulk should pass. Such was a rough outline of this case of catheter fever. And now came the important question:

WHAT WAS THE CAUSE OF THE CATHETER FEVER?

Before dealing with that question we would call to mind a few important points. Before the introduction of the catheter this man was in average good health. He was aged sixty-five years, and quite well. He had ceased to have daily necessary work to do—the worst thing that could happen to a man! The second point was that the constitutional disturbance was the first thing that attracted the attention of those around him. After the introduction of the catheter he was ill. The third point was the curious order in which the local symptoms appeared. The first was burning pain in the urethra, then the excessive irritation of the bladder, and lastly, the affection of the kidneys. The fourth point was that the constitutional symptoms were out of all proportion to the intensity of the local malady. At one time, on the third day, these were so bad that the patient appeared to be about to die, and yet when everything was examined there was nothing to account for this condition, for at no time had the percentage of urine fallen below 1.5. The last point was that bacteria did not appear at the beginning of the malady. It was not until the third day that the bacteria were found in the urine, and it was not until the fourth day that they were found in very great numbers. What was the cause of the catheter fever in this case? Those who are experienced in urinary disorders say, in the most dogmatic manner, that every man who had catheter fever must have had long-standing urinary disease, and if you had not introduced the catheter at all he would have died very soon notwithstanding. Was that the case in this instance? They had testimony of his good health, that the urine was declared to be healthy before the introduction of the catheter, and thirdly, that there was no evidence of old urinary disease. The only evidence they had was evidence of the existence of a gouty diathesis. The conclusion they came to was that this catheter fever was septic fever, and that in every case in which it occurred its origin might be traced to the introduction of parasites or germs into the blood. In seeing this case from the beginning they took care to investigate this matter. They got the old clock oil. The smell of it was not as pure as it should be. They expected to find an abundant growth of micro-organisms, but their anticipations were falsified. They put along with the oil a drop of urine, and in twenty-four hours the whole was thick. It was quite clear that septic infection—parasitic infection—was not the cause in this case. There was no sort of septic infection which was not parasitic. It had been shown within the last three or four years that in certain conditions organisms were developed, which, when coming in contact with the living tissue begot symptoms of poisoning and fever. But this was quite different from this catheter fever. Was it possible that the catheter fever was developed from one of these poisons instead of from a septic poison? His impression was that the formation of any of these substances could not have been the cause of the catheter fever. Then, if it was not due to previous disease, or parasitic infection, what could it be? Was it pyæmia? Was it due to injury to the urethra? The urethra was painless. He was obliged to fall back upon the explanation he gave at Edinburgh. He would give it as it appeared to him in the mode of development. First, there was the pain and local irritation, followed by the introduction of the catheter. He believed the irritation of an organ or tissue might be brought about, and the greatest changes follow without the patient being conscious of it. The local irritation, felt or unfelt, would be continued to the central sympathetic and organic centres, the provocation thereby to disorderly reflex nervous discharges producing disturbance of the vascular system. Thirdly, connected with these were the pathogenetic nerve-discharges, and the changes of the blood and excrementitious masses of various kinds.

Mrs. Garrett Anderson, M.D., described a case of

INCONTINENCE OF URINE

in a girl of fourteen, who had been under the care of Dr. Annie Clarke, at the Birmingham Hospital for Women. The incontinence was of several years' standing, and dated from an attack of scarlet fever at the age of six, when some ulceration took place leading to a communication between the bladder and the vagina and the formation of adhesions. The condition was ultimately remedied by a plastic operation.

Mr. Jordan Lloyd read a paper on

INFLAMMATION OF THE SEMINAL VESICLES.

This affection was one most common in young adults as a result of gonorrhœa. He mentioned several cases which had come under his notice. There was pain on defecation, and constitutional disturbance, with constant desire to micturate. Examination per rectum showed the presence of a swelling at the base of the bladder, very tender to the touch. Suppuration often followed, and in such cases his plan was to incise through the rectum. All the cases so treated did well.

Dr. Ward Cousins, of Portsmouth, exhibited a new excavator for lithoplaxy and other bladder operations. Mr. Hurry Fenwick read a paper entitled "Notes from the Experiences of Five Hundred and Fifty Cases of Organic Stricture of the Urethra." Dr. Hugo Marcus, of Paris, read a paper "On the Causes of Suppuration" Mr. E. Stanmore Bischof, of Manchester, referred to some forms of osteotomy, and showed an apparatus for fixing the lower limbs after division of the bones.

Mr. Mayo Robson read a paper on a series of cases of

MACEWEN'S OPERATION FOR GENU VALGUM.

He thought these cases arose more from ignorance than from negligence. They were very prevalent in Glasgow and Leeds. He suggested that more attention should be given to house visitations, and that houses for the poor should never be built on the back-to-back principle.

(To be continued.)

Pruritus Pudendi is often relieved, according to Dr. Routh, by applications of peppermint water.

Correspondence.

TREPHINING THE SPINE.

To the Editor of The Medical Record.

Sir: In The Medical Record of August 25, 1888, I find an editorial on "Trephining the Spine for the Relief of Pott's Paraplegia," in which the writer rather strongly discountenances this operation, and thinks that the hope is not justified that operative procedure may give permanent relief. He refers to Ashhurst's table,[1] according to which forty-three cases of resection of the spine have been performed on account of various injuries (not stated), with the result that only four were relieved, while thirty-one (seventy-two per cent.) died, four were not benefited, and the result was unknown in five cases. Lastly, the writer says, referring to the case reported, that it is interesting as showing the inutility, and therefore the unjustifiability, of operation in such cases, etc. The present writer takes the liberty of disagreeing with these sweeping statements, and for various reasons. The forty-three cases referred to are old and useless, in so far as most of them, if not all, date from the pre-antiseptic period. Some of them were done more than fifty years ago. I fail to see why a resection, done *lege artis* and with all proper precautions, should be more dangerous than trephining of the skull, an operation which scarcely any surgeon of experience considers dangerous *per se* in our days. The difficulty lies in the fact that it, in a given case, is almost impossible to decide whether the medulla is crushed (and the operation therefore useless) or simply compressed.

So far from considering the operation useless, I am strongly inclined to the belief that it alone offers any hope of relief from the paraplegia and all the other severe symptoms depending upon the same cause, and the operation itself I consider neither particularly dangerous nor difficult. There is, you know, more joy in heaven over one sinner that repenteth than over ninety-nine just persons that need no repentance, and this sinner's record you can find in *Centralblatt für Chirurgie*, 1886, No. 51, and I shall give a short extract of the case. He was a Norwegian sailor who, five weeks previous to his entrance into the Marine Hospital in Hamburg, of which Dr. Carl Lauenstein is the surgeon, fell forty feet, lay twelve hours unconscious, and since had been completely paralyzed in the lower extremities, with paralysis of the sphincteres ani and vesicæ. He had a gibbosity of the lower dorsal and upper lumbar vertebræ, the processus spinosis of the twelfth dorsal vertebra being most prominent. Dr. Lauenstein applied a plaster-of-Paris jacket for four weeks, but as the patient grew worse, on account of cystitis, operation was performed, and the arches of the twelfth vertebra dorsi and first vertebra lumbalis were removed. The medulla and cauda were found just beneath the arches, adherent to the dura, of which a piece was removed. The wound healed by first intention. Five days later the patient commenced to have some control over his bladder, which gradually increased. Ten days after the operation the anæsthesia commenced to diminish. Inside two months he was able to walk with a stick, and three months later he could walk up and down stairs without support, and was shortly afterward discharged about cured. The paralysis of the sphincteres had disappeared and only the sensibility of the right femur was somewhat lessened. Lauenstein advises not to operate in fresh cases, as there is a possibility that the paralysis may disappear by itself. But in cases in which, after eight weeks, there is no improvement, particularly of the sphincteres, he advises the operation.

One such successful case ought to give this operation quite a stimulus and, anyway, speaks volumes more than a table of unsuccessful cases, operated upon without modern antiseptic precautions. I myself last year performed a similar operation which, although unsuccessful, I desire to add. The patient was a man, aged fifty-two, who entered the Buffalo General Hospital in June, 1887. On June 4th, while suffering from delirium tremens, he jumped out of a second-story window and fractured his back. He was immediately completely paralyzed in both lower extremities, both in regard to motion and to sensibility. The sphincteres ani and vesicæ were paralyzed too. A plaster-of-Paris jacket was applied the same day and kept on for four weeks, but the patient did not improve. A severe cystitis developed, bed-sores made their appearance, and the patient was rapidly failing. As a last measure, the arches of the twelfth dorsal and first lumbar vertebræ were resected on July 5th. The dura was found strongly adherent to the arches, and a piece of it was removed. Through the opening made, about a tablespoonful of the cerebro-spinal fluid was evacuated. The body of the twelfth vertebra was found fractured and dislodged backward into the medullary canal, and the medulla spinalis was found bent in an acute angle over this body and torn more or less. The wound was dressed after Schede's blood-clot method, but the patient survived but two days. The operation showed the injury to be incurable, but the operation itself was harmless. I do not believe that it in any way shortened his life, and in a similar case I should feel strongly inclined to repeat the attempt.

Herman Mynter, M.D.

Buffalo, N. Y., August 29, 1888.

JAUNDICE.

To the Editor of The Medical Record.

Sir: In Dr. Kittrell's article, "Treatment of Catarrhal Jaundice," in a recent issue of The Medical Record, I was struck with the statement that a form of jaundice might result from *suppression*, and that the cause of the bile acids appearing in the urine in a case due to *obstruction*, and not in one due to *suppression*, was their non-formation in the liver when suppression existed, the opposite condition obtaining in obstruction. The latter explanation is correct in all its bearings, but as to the theory of suppression, I am impressed that it is wholly erroneous. This theory was once held by Trousseau, Bamberger, Watson, and other eminent authorities, but it has within late years been entirely abandoned. In order to prove the theory of suppression, it would have to be shown that the bile existed preformed in the blood. Now the most important constituents of the bile are the acids, taurocholic and glycocholic, and the pigment, and it is pretty conclusively shown that these are formed in the liver, and also that hæmatoidin and bilirubin are not identical.

It is true, water, cholesterin, fat, and inorganic salts pre-exist as such in the blood, and are eliminated from the latter by the liver-cells. The biliary salts and the biliary pigment, however, are not found in the blood, but are elaborated by the liver-cells out of the principles brought to them by the blood (Chapman, "Physiology") The experiments of Stein fully corroborate this view. He has shown that if the blood-supply to the liver be cut off, there is no accumulation of the bile-acids and bile-pigment in the fluids and tissues of the body. Thus it is shown jaundice cannot result from suppression.

If jaundice could result from suppression, thus establishing the fact that bile exists preformed in the blood, then the differential diagnosis made by the test of Pettenkofer, employed by Dr. Kittrell, as regards the presence of bile-acids in the urine, would be *nil*, as in such a case the bile would be taken up entire and eliminated by the urine, and the presence of the acids there detected. This is known not to be the case.

The varieties of jaundice now arrived at are two. The one, a cholæmic, results from the presence in the blood of the acids and pigment of the bile; this is the hæmatogenous, anhepatogenous, or hæmoglobinæmic form. The other is the obstructive or hepatogenous form, and results from the absorption of the bile already formed, whose escape cannot be effected owing to obstruction in the hepatic ducts or in the ductus communis chloledochus, or to some vaso-motor influence.

---

[1] International Encyclopædia of Surgery, vol. iv., p. 890.

The hæmatogenous variety, the theory of which has replaced that of suppression, is due to the presence of free blood-pigment in the blood. According to Ponfick, this may be as granular, disintegrated red blood-corpuscles or as dissolved hæmoglobin. The cutaneous jaundice is the result of the transformation in the blood of hæmoglobin into bilirubin. It occurs when more blood-pigment is set free than can be disposed of by the spleen, liver, or kidneys.

I trust this will convey only the impression of a disposition to place aright the subject under consideration, feebly as it approaches this aim, and not merely to find fault with the author whose valuable paper contains much that is good. G. M. CORCORAN.

UNIONTOWN, ALA.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 2 to September 8, 1888.

A Board of Medical Officers, to consist of CHARLES H. ALDEN, Major and Surgeon; GEORGE M. STERNBERG, Major and Surgeon; HENRY MCELDERRY, Major and Surgeon; EDWARD C. CARTER, Captain and Assistant-Surgeon, is constituted to meet in New York City on October 1, 1888, or as soon thereafter as practicable, for the examination of assistant surgeons for promotion, and of candidates for admission to the Medical Corps of the Army. S. O. 203, A. G. O., September 1, 1888.

ALDEN, CHARLES H., Major and Surgeon. Detailed as a member of the Board of Medical Officers convened at U. S. Military Academy, West Point, N. Y., vice Major Charles R. Greenleaf, Surgeon, relieved. Par. 2, S. O. 199, A. G. O., August 28, 1888.

CALDWELL, DANIEL G., Major and Surgeon. To report to the Recorder of the Retiring Board in session at Fort Leavenworth, Kan., as a witness in the case of Captain Thomas Sharp, Seventeenth Infantry. Par. 2, S. O. 74, Department of the Platte, August 18, 1888.

CALDWELL, DANIEL G., Major and Surgeon. Having completed his duty as witness before Retiring Board, Fort Leavenworth, Kan., to return to his station, Fort D. A. Russell, Wyo. Terr. Par. 4, S. O. 106, Department of the Missouri, August 24, 1888.

LORING, LEONARD Y., Assistant Surgeon. Granted leave of absence for one month. Par. 1, S. O. 97, Department of Arizona, August 23, 1888.

TAYLOR, MARCUS E., Captain and Assistant Surgeon. Granted leave of absence for four months, to take effect about October 15, 1888. Par. 8, S. O. 196, A. G. O., August 24, 1888.

BIRMINGHAM, HENRY P., Captain and Assistant Surgeon, relieved from duty at Fort Myer, Va., and ordered to Fort Klamath, Ore. for duty. Par. 18, S. O. 196, A. G. O., August 24, 1888.

BALL, R. R., Assistant Surgeon, Fort Riley, Kan., ordered to Fort Lewis, Col. for temporary duty. Par. 5, S. O. 108, Department of the Missouri, August 27, 1888.

SWIFT, EUGENE L., Assistant Surgeon. Upon being relieved from temporary duty at Fort Klamath, Ore., to return to his proper station, Fort Spokane, W. T. Par. 18, S. O. 196, A. G. O., August 24, 1888.

RAFFERTY, OGDEN, Assistant Surgeon. To proceed from Fort Clark to the camp at the Department Rifle Range, near San Antonio, Tex., and report for temporary duty. Par. 3, S. O. 85, Department of Texas, August 15, 1888. Upon conclusion of Department Rifle competition will report to the Inspector of Rifle Practice, Division of the Missouri, for assignment to duty in connection with the Division rifle competition as Camp Surgeon. Par. 4, S. O. 86, Department of Texas, August 17, 1888.

WORTHINGTON, J. C., Captain and Assistant Surgeon. Ordered from Fort Crawford, Col., to Fort Townsend, W. T. S. O. 206, A. G. O., September 5, 1888.

HALL, J. D., Captain and Assistant Surgeon. Ordered from Fort Townsend, W. T., to Fort Niagara, N. Y. S. O. 206, A. G. O., September 5, 1888.

BROWN, P. R., Captain and Assistant Surgeon. Ordered from Fort Niagara, N. Y., to Fort Sidney, Neb. S. O. 206, A. G. O., September 5, 1888.

Official List of Changes in the Medical Corps of the United States Navy for the week ending August 25, 1888.

SIMONS, MANLY H., Surgeon. Detached from Constellation, and ordered to the Naval Academy.

RUSSELL, A. C. H., Passed Assistant Surgeon. Detached from Constellation, and ordered to the Naval Academy.

DICKSON, S. H., Passed Assistant Surgeon. Detached from Marine Barracks, Washington, D. C., and ordered to the U. S. S. Richmond.

CORDEIRO, F. J. B., Passed Assistant Surgeon. Ordered to the U. S. S. Mohican.

FARWELL, W. G., Surgeon. Detached from the U. S. S. Saratoga, and ordered home to wait orders.

DICKINSON, DWIGHT, Surgeon. Detached from the U. S. S. Portsmouth, and ordered home to wait orders.

CRANDALL, R. P., Assistant Surgeon. Detached from the Saratoga; to wait orders.

DUBOSE, W. R., Passed Assistant Surgeon. Detached from the Jamestown, and ordered to the Constellation.

ARNOLD, W. F., Nashville, Tenn. Commissioned Assistant Surgeon in the Navy, August 18th.

LUNG, GEORGE A., Canandaigua, N. Y. Commissioned Assistant Surgeon in the Navy. August 18th.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 8, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	66	14
Scarlet fever	60	16
Cerebro-spinal meningitis	2	3
Measles	80	4
Diphtheria	53	18
Small-pox	1	0
Yellow fever	0	0
Cholera	0	0

SUCCI, THE ITALIAN FASTER, is still at work giving exhibitions of his ability to abstain for long periods from food, and submitting his excretions to the physiologists for examination.

The Treatment of Carbuncle.—Dr. F. D. Reese, of Cortland, N. Y., writes: "I have seen in The Medical Record, of late, two or three articles describing and recommending the use of carbolic acid in the treatment of carbuncle. While a student in Long Island College Hospital, the treatment for this disease, as given by Prof. Wight, was to apply carbolized oil to the diseased part and then cover with oakum, which had previously been saturated with the oil. Since I have been practising I have had a few cases of carbuncle which I have treated in this way, and not one has run over two weeks. The disease has yielded to the carbolized oil and oakum treatment as by magic. I have used a twenty per cent. solution."

"Revista Brazileira de Medicina" is the name of a bimonthly journal born in Rio de Janeiro with the year 1888. It is published under the direction of Dr. Azevedo Lodré. If the subsequent numbers fulfil the promise given by the first the *Revista* cannot fail to succeed.

Peganum Harmala.—This is a plant belonging to the rue family, growing wild in Egypt, Spain, and the Crimea, and which is often cultivated in other parts of Europe for its pretty white flowers. The odor of the whole plant is, however, disagreeable. Two alkaloids, harmaline and harmine, have been extracted from the seeds. The former crystallizes in yellow scales soluble in alcohol, but scarcely at all in ether or water; harmine crystallizes in small colorless needles almost insoluble in water, alcohol, and ether. Dr. Paudurel has experimented with an infusion and a tincture of peganum seeds, and has found the drug to be possessed of decided emmenagogue properties, but causing also a slight intoxication similar to that from hasheesh. The dose of the tincture is one-half drachm.—*Gazzetta Medica Italiana.*

A Curious Case of Malingering.—Mr. A. Pearce Gould reports in *The Lancet* of June 2, 1888, the case of a servant girl, aged twenty, who was brought to him for advice concerning a supposed tumor in each cheek. One surgeon, who had seen the girl, pronounced her case a hopeless one, and another had advised excision of the neoplasms. On everting the lip a gray surface resembling a slough was seen, but the introduction of the finger showed that the "tumor" was nothing but a ball of calico cloth, very tightly rolled, placed between the jaw and the cheek. No motive for the deception could be discovered.

Glycosuria from Salicylic Acid.—Dr. F. W. Burton has examined the urine of twelve patients under the influence of salicylic acid, salicylate of soda, or salol, and has found sugar in varying amounts in every instance. He believes that the salicylates act upon the diabetic centre, and that the benefit occasionally seen to follow their administration in diabetes mellitus may be due to the opposite action of small and large doses, as is seen in the case of some other drugs.—*The Lancet.*

Intra-pleural Injections of Sterilized Air.—M. Potain, in a communication made to the Academy of Medicine of Paris, on April 24, 1888, described a method from which he had obtained very satisfactory results in the treatment of pneumothorax. It consists in the complete evacuation of the fluids in the chest and the substitution of sterilized air. This obviates, he claims, the danger attendant upon a rapid evacuation of the pleural cavity, prevents further suppuration, does away with the necessity of repeated punctures, and gives to the lung needed repose, thereby favoring the cicatrization and definite cure of the tubercular lesions.

Hydrate of Amylene.—This substance is a colorless watery-looking fluid, having a sharp taste and smell, which was discovered by Von Mehring and Thierfelder to possess a marked hypnotic action. Its action may be summed up as follows: 1. Hydrate of amylene is a hypnotic whose action can be confidently relied upon when sufficiently large doses are given. Experiments have shown that it is not so strong as chloral, yet stronger than paraldehyde. 2. Hydrate of amylene also acts upon persons who are accustomed to the use of hypnotics, although the dose employed in such cases must be comparatively large. 3. Sleep occurs soon after the administration of the drug, and is not preceded by any period of excitement. The sleep produced is light or heavy, according to the dose given; yet it is always easy to awaken the patient. Upon waking the patient is perfectly sensible and bright, but if not disturbed further will at once fall asleep again. 4. Sleep lasts from two to three hours if small doses have been given, or from six to eight hours under the influence of larger doses. 5. The awaking is similar to that from natural sleep. The patients feel rested and strengthened. No headache or weakness was ever observed. 6. The respiration remains unchanged. 7. The change in the pulse's frequency and in the pressure of blood is no more than that which accompanies natural sleep. 8. The patients were never observed to wake up with a bad taste in their mouths and complaining of a disagreeable smell, symptoms which nearly always follow the use of paraldehyde. 9. Whether or not a habit and tolerance for the drug may be formed remains yet to be seen. As yet, even when the drug has been used continually, an increase of dose was never found necessary. The drug may be given in gelatine capsules, or in fluid form mixed with claret or raspberry syrup and water. The average dose is about half a drachm.—*Therapeutic Gazette*, May 15, 1888.

A Parasitic Monstrosity.—There is now on exhibition in London a boy, aged seventeen, from Oudh, named Laloo, to whose abdomen is attached an incomplete body consisting of the upper and lower extremities, which are, however, entirely separate from each other. The shoulder girdle has the arms attached and shows the nipples. The pelvic extremity presents the buttocks and legs. The pelvic region is covered with hair, and there is a well-formed penis from which urine escapes involuntarily. The anus is apparently imperforate. Both the upper and lower extremities are deformed. The temperature of the parasite is apparently lower than that of its carrier.

Treatment of Urticaria in Infants.—In infantile urticaria, Dr. Deligny recommends the inunction, every evening, of the following ointment; ℞. Chloral hydrar., pulv. camphor, pulv. gum. acaciæ, āā 4 parts; ung. simplex, 30 parts. Rub the first three substances together until liquefaction occurs, and then add the simple ointment. This combination calms the itching, allows the child to obtain sleep, and does away with the scratching which gives rise to such distressing effects in this disease. In the morning the skin should be anointed with a one per cent. mixture of carbolic acid in glycerine of starch. —*London Medical Recorder.*

Treatment of Constipation in Women.—When constipation exists in women who menstruate profusely, as in rheumatic subjects, equal parts of flowers of sulphur and calcined magnesia, mixed with an equal bulk of cream of tartar, will be found an excellent laxative.—*Medical Recorder.*

Diphtheria from a Fowl.—Dr. Hoadley Gabb reports the following case (*British Medical Journal*, July 21, 1888): A fowl with diphtheria was brought to the house of a veterinary surgeon on April 24th, and died on the 29th. The feeding and nursing of the bird devolved on a lad, aged fourteen, who was assisted by his brother, aged five. On the evening of May 11th the writer was called to see the little boy of five, who had been poorly for a day or two. He had enlarged cervical glands on the left side, which had come on rapidly. He was a delicate little fellow, with fair hair and anæmic aspect. The temperature was 103° F.; pulse, between

120 and 130. The fauces were more or less covered with diphtheritic membrane, the left tonsil more especially. Under the administration of biniodide of mercury and iron the throat symptoms cleared up, and the child made a good recovery. On the day after this case was first seen the boy who fed the fowl was very feverish, and had similar patches over his fauces, but not to the same extent as his brother. His throat was painted with boroglyceride. A sister, aged nine, had also a similar explosion on the fauces. Bark and acid and boroglyceride was the treatment. On the 18th the mother, who had nursed them, was attacked, and was similarly treated. They were all kept well up with beef-tea and stimulants.

Chloride of Sodium in Heart Failure. — Dr. Rosembusch gives hypodermic injections of a six per cent. solution of chloride of sodium, to which a trace of caustic potash has been added, in cases of heart failure. The quantity injected varies from two drachms to an ounce and more.

Caffein in Heart Failure.—Dr. de Gempt writes (*Berl. klin. Woch.*, Nos. 25 and 26) in support of the employment of caffein (mostly in the form of the bisalt, "caffeinum natrosalycilinum") hypodermically and by the mouth in cases of threatening collapse, especially in pneumonia. He records several such cases, but, in all, other stimulants, as alcohol, ether, and ammonia, were more or less freely given. The dose of the caffein was 0.35 grm., repeated four or five times a day, but sometimes a larger quantity —*e.g.*, 0.2 grm.—was given. The author says that the drug is indicated in the course of acute pneumonia, as soon as there is evidence of cardiac failure, lowered arterial pressure, great rapidity or irregularity of the pulse. The administration of the drug should be commenced if possible before the onset of collapse ; but even if the latter condition set in rapidly the drug is often of use, and is most urgently indicated. Where there is cardiac debility, and also in the very young or old, caffein may be prescribed from the beginning of the attack. The result of its employment is to cause a diminution in the pulse and respiration rates, an increase of the arterial pressure, with fall of temperature and general improvement. Stimulants are not to be withheld, but are often very usefully given in conjunction with the caffein. The drug has a very rapid action, and in serious cases the effect may be still more quickly produced by administering it subcutaneously. It may be continued for a short time after the pyrexia has abated. Caffein is also indicated in collapse and hypostatic congestion.—*The Lancet.*

Naphthalin Enemata in Dysentery. — Naphthalin has been employed internally by many observers with very satisfactory results in the summer diarrhœa of children, and in other catarrhal conditions of the intestinal mucous membrane which depend probably on the presence of microbes of one kind or another. A Russian practitioner, Dr. Gintergoff, now writes in the *Russkaya Meditsina* (No. 21) that he has found injections of this drug most valuable in the few cases of dysentery in adults in which he has made use of them. He orders seven or eight grains in an ounce of water for a single enema, and finds that this in a very short time relieves the tenesmus and the burning sensation at the anus. The patient is able to obtain rest and sleep, and in some cases is cured without any repetition of the enema. In other cases two or three enemata have to be given at intervals of a few hours. Where needful this treatment is combined with the internal administration of quinine.—*The Lancet.*

In "The Spleen," a poem written by Matthew Green some hundred years ago, occurs the following suggestion for the "blues:"

"To cure the mind's wrong bias, Spleen,
Some recommend the bowling green ;
Some hilly walks ; all exercise ;
Fling but a stone, the giant dies."

The Immortal Daviel.—In our Paris letter, published in the issue for May 26th, the last word should have been printed Daviel instead of David.

Displacement of the Optic Nerve.—A correspondent reports a conversation overheard in a railroad depot between two ladies. The first was relating her sorrows when the second interrupted her with the remark that she knew just how she felt, for she herself had suffered greatly, the optic nerve in the back of her neck being so swollen that she could not turn her head. She had, however, obtained relief from Dr. Blank's magic cure, and off the two went to the nearest drug store for a bottle of the optic-nerve restorer.

Painted and Powdered Children.—Parisian mothers, according to *The Lancet*, are not content to see their children healthy looking, but have called in the aid of dyes and powders to impart what they consider to be a still more becoming complexion.

International Otological Congress. — The next International Congress of Otology will be held in Brussels on September 10th to 16th, under the presidency of Dr. Delstanche. The Secretary of the Congress is Dr. Goris, of Brussels.

A Doctor Awakened by his Night-bell.—A Berlin physician, so states the *Central Zeitung*, was awakened one night by the violent ringing of his bell, and on opening the door found his landlord's servant who had been belated and took this means of gaining an entrance. As neither the servant nor her master seemed to regard the matter as anything out of the way, the irate doctor caused her arrest on the charge of trespass, and the court imposed a fine of seventy-five cents and costs. Several physicians of this city, living in flats, who have had a similar experience, may be pleased to learn of this legal decision.

The Pirogoff Surgical Society has received a grant of land from the municipality of St. Petersburg on which to erect a central medical building. This edifice is to contain a large hall, in which will be held the meetings of all the medical societies of the capital, accommodation for the combined libraries of these societies, and also a surgical ward of ten beds. The building is to be erected upon the Preobrajenski Square.

An Elaborate Dressing for the Umbilical Cord. —Dr. Fagonski, after tying and dividing the umbilical cord, powders the surface of the stump with plaster-of-Paris, covers it with absorbent cotton, strews a little more gypsum over this, and then applies a retentive bandage. In this way he obtains a dry mortification of the stump, and prevents, he believes, all diseases of the umbilicus in infants.—*Vratch*, No. 11, 1888.

The Fatal Dose of Boracic Acid is, according to Gaucher, two and one-half ounces daily, continued for at least ten days.

Migranous Headache is best relieved, according to Dr. Little (*Dublin Journal of Medical Science*, June, 1888), by twenty grains of salicylate of sodium in a wineglassful of water made effervescent by the addition of a dessertspoonful of granular citrate of caffeine. The latter alone Dr. Little has not found efficacious.

Deafness from Stimulation of the Retina.—A curious phenomenon was recently related by M. d'Arsouval before the French Academy of Medicine. After gazing for a few seconds on an arc light of intense brilliancy, he suddenly became deaf, and remained so for nearly an hour and a half. Surprised and somewhat alarmed in the first instance, but reassured by the disappearance of the symptoms, he repeated the experiment with the same result. When only one eye was exposed to the light no very marked effect was produced.—*Medical Press and Circular*, June 13, 1888.

Vol. 34, No. 12 NEW YORK, SEPTEMBER 22, 1888 Whole No. 933

Society Reports.

Congress of American Physicians and Surgeons.

First Triennial Meeting, held at Washington, D. C., September 18, 19, *and* 20, 1888.

TUESDAY, SEPTEMBER 18TH—FIRST DAY—MORNING SESSION.

THE meeting to receive the report of the Executive Committee and for Organization was held at 1 P.M., Tuesday, in the Grand Army Building.

The meeting was called to order by DR. WILLIAM PEPPER, Chairman of the Executive Committee, who spoke as follows:

"On behalf of the Executive Committee, I have to announce the manner in which we have discharged our responsible duty. The present meeting is the result of prolonged deliberation, which began to take shape more than four years ago, before the attention of the medical profession became occupied with preparations for the meeting of the International Medical Congress; but all action was deferred in order that there should not be the semblance of interference with that important meeting. This delay has served to render more conspicuous the necessity for this organization.

"Your Committee venture to hope that their provisions will meet the unanimous approval of the Congress. We have recommended that the sessions shall be triennial. We have jealously guarded against the admission of parliamentary business, since the functions of the Congress are designed to be absolutely or exclusively scientific. We have also guarded the independent sovereignty of each participating society.

"The Executive Committee has reached the conclusion that the selection of the President of each Congress shall be intrusted to the Executive Committee then in office. Close study of the conditions of this Congress has led this Committee to feel that if this organization were to have the effect of favoring the multiplication and subdivision of special societies it would be nothing less than a calamity. We have therefore provided that the admission of new associations shall be secured only by the unanimous vote of the Executive Committee.

"It remains only to add that in exerting the privilege of selecting a President for the first Congress of American Physicians and Surgeons, I feel that we have been guided to the choice of a man, whose admirable personal character, whose high attainments, and whose illustrious services in the cause of literature, of science, and of the entire medical profession, mark him as entitled to this great honor and distinction.

"It gives us, therefore, the utmost gratification to present to you our President, Dr. John Shaw Billings, and to announce that the Congress of American Physicians and Surgeons is now duly organized."

DR. J. S. BILLINGS, as President of the Congress, then took the chair and responded in a brief address.

DR. SAMUEL C. BUSEY, of Washington, then made an

ADDRESS OF WELCOME,

in which he dwelt upon the beauties of Washington, and the advantages which it offered as a place of meeting for scientific societies.

The following

BY-LAWS

were then adopted:

1. This organization shall be known as the Congress of American Physicians and Surgeons.
2. It shall be composed of National Associations for the promotion of medical and allied sciences.
3. It shall hold its sessions tri-annually in the City of Washington, D. C.
4. The officers of the Congress shall be a president, vice-president, a secretary, a treasurer, and an executive committee.
5. The president shall be elected by the executive committee, of which he shall ex officio be a member. He shall preside at the sessions of the Congress. He shall deliver an address.
6. The presidents of the participating societies shall be ex officio the vice-presidents of the Congress.
7. The secretary and treasurer shall be elected by the executive committee. They shall be ex officio members of the executive committee.
8. The executive committee shall be composed of one member from each participating society; and said member shall be elected by the various societies at the next annual meeting subsequent to the Congress. It shall be charged with all duties pertaining to the organization of and preparation for the ensuing Congress, including the election of all officers, and of a committee of arrangements. It shall superintend the publication of the Transactions of the Congress.
9. The expenses of the Congress shall be divided between the participating societies in proportion to their membership.
10. The admission of new associations to participation in the Congress shall be by unanimous vote of the executive committee.

EVENING SESSION.

J. S. BILLINGS, PRESIDENT, IN THE CHAIR.

DR. REGINALD H. FITZ, of Boston, opened the discussion upon

THE MEDICAL RELATIONS OF ACUTE INTESTINAL OBSTRUCTION.

The subject of this paper was the diagnosis and medical treatment of the acute internal, mechanical varieties of intestinal obstruction. The only causes recognized were strangulation from adhesions, vitelline remains, peritoneal slits, pockets, and rings; intussusception, twists and knots, abnormal contents, strictures, and tumors. The evidence presented resulted from an analysis of two hundred and ninety-five cases collected from medical literature since 1880.

The most constant symptoms of obstruction were shown to be pain, vomiting, tympany, and tumor. Stoppage of the bowel was not regarded as the most essential symptom in diagnosis, since frequent loose stools characterize intussusception, and may occur in other varieties of obstruction. Too much attention directed to this symptom leads to erroneous diagnosis, since it is of frequent occurrence in peritonitis, and often results in irrational and injurious treatment. The physician is called upon to decide whether the given case is one of acute obstruction; then where its seat, and what its cause, and, finally, what is to be done. The evidence offered showed that the diagnosis was to be made by excluding the various causes of peritonitis. Its seat in the large or small intestine was to be determined by injections under high pressure when necessary. The variety was for most practical purposes an intussusception, or a twist of the large intestine and strangulation, or gall-stones in the small intestine. The differential diagnosis depended on the relative frequency of these varieties, the age of the patient, the antecedents, and immediate symptoms.

The treatment consisted in the attempt to relieve intussusception of the large intestine by forced injection under anæsthesia, with massage, and to treat obstructing gall-stones by opium, possibly with the aid of laxatives and electricity. All the other varieties of acute obstruction require surgical treatment. The latter treatment is also necessary on or before the third day in cases of intussusception not yielding to forced injections, and in gall-stones when the symptoms become urgent.

Dr. Nicholas Senn, of Milwaukee, then read a paper on

THE SURGICAL TREATMENT OF INTESTINAL OBSTRUCTION.

He claimed at the very beginning that all cases of true intestinal obstruction are, in every sense of the word, surgical affections. Intestinal obstruction is present when, from mechanical or from dynamic causes, the intestinal canal becomes completely or partially imperforate. interfering completely or partially with fecal circulation. It is important that a distinction be made between the cases due to mechanical causes and those due to dynamic causes. In the former the surgeon is expected to modify the mechanical cause, in the other the surgical treatment is limited to diminishing intra-abdominal pressure. Cases of internal intestinal obstruction should be considered in the same light as cases of strangulated hernia. Operation should be performed as soon as the diagnosis is made.

The surgical resources in the treatment of internal obstruction were taken up *seriatim.*

Irrigation of the stomach.—All forms of intestinal obstruction, no matter what the cause, are aggravated by anything that increases the hydrostatic pressure on the proximal side of the obstruction. Irrigation of the stomach relieves this, and also diminishes the intra-abdominal pressure. This measure should always be performed before operation, as it prevents vomiting. An antiseptic solution should be used in the irrigation.

Distention of the intestine with fluids.—The mechanical effects of this measure are limited to the colon, the fluid does not pass beyond the ileo-cæcal valve. Why should we not in these cases resort to the lightest possible substance known, hydrogen gas, which is harmless, readily obtained, and aseptic?

Manual exploration by the rectum is a useful diagnostic and therapeutic measure where the obstruction is below the sigmoid flexure, provided the surgeon has a small hand.

Taxis and massage should be limited to cases where the obstruction is due to intramural causes, and to a few cases of invagination. Uniform, uninterrupted, equable *pressure of the abdomen* is useful in preventing hyperdistention in these cases, especially when dynamic causes are feared.

Enterotomy, so frequently practised in the past, he hoped had become very nearly obsolete. It should only be employed when it is clear that the patient will not be able to pass through the ordeal of laparotomy.

Lumbar colotomy.—In cases where this operation was formerly employed we can often, by uniting the portion of the bowel above the obstruction with that below, by means of decalcified bone-plates, avoid the necessity for colotomy. I have specimens showing that a dilated, congested bowel can be repaired when excluded from the fecal circulation in this way.

The author had, in the past eight months, performed gastro-enterostomy in four cases by this method. In all of these cases the operation was a success, although in one case the patient died because the operation had been postponed too long. Gastro-enterostomy in incurable carcinoma is a safe operation, and one which the surgeon owes to all such patients.

(The time allotted to this portion of the discussion having expired, the speaker was unable to complete his remarks.)

Dr. Arthur Durham, of London, had taken much interest in this subject; there is no class of cases which are more serious or more dangerous than those of intestinal obstruction. He agreed with Dr. Senn that usually in these cases the sooner the surgeon is called, the better. As soon as the diagnosis is made the operation should be performed. In some cases it should be done before a positive diagnosis is reached, and in order to clear up the diagnosis. Under such circumstances the surgeon must be prepared to meet the indications that present themselves. In trying to reach a diagnosis the probabilities in favor of this or that condition, based upon statistics, should not influence us; but the case should be studied on its own merits, and treated on the indications before you. In regard to the injection of hydrogen gas, he suggested the possibility of the formation of explosive compounds, and thought that atmospheric air might be substituted.

Dr. William Ord, of London, admitted that there was often a great deal of difficulty in the diagnosis. He was in favor of the views of Dr. Fitz, and claimed a little time before resorting to operation. In some of these cases, under the use of opium and time, the cause of obstruction had disappeared. Where, however, there is mechanical obstruction the case must sooner or later go into the hands of the surgeon. This time should be a short one. The operation is a serious one, especially in people over fifty years of age. He had often seen the operation performed, and frequently fail in those cases where there was the most reason to expect success.

Professor Thomas Annandale, of Edinburgh, said that these cases of obstruction should be divided into two classes, the acute and the chronic. In acute cases medical measures should be tried, but not continued too long. If the symptoms are urgent, the surgeon should be called at the end of forty-eight hours; the sooner the abdomen is opened the better. In the chronic cases we may wait a considerable time, even until the symptoms become acute; the treatment should then be that applicable to a case of acute obstruction. He had largely given up lumbar colotomy, which he had employed more particularly in rectal obstruction, and resorted to inguinal colotomy, as a simpler and not more serious operation in most cases.

Dr. Senn, in closing the discussion, stated that there was not the least danger in the use of hydrogen gas. He had performed many experiments on animals, and had used the procedure in man. In cases of intestinal perforation it aids the diagnosis, and allows the surgeon to determine whether or not all the openings have been closed. In a recent case of gunshot wound eleven openings near the ileo-cæcal valve were closed, and a twelfth was revealed by the hydrogen gas, at the point where the peritoneum is reflected from the bowel to the bladder. The patient is doing well one week after the operation.

Dr. Roswell Park, of Buffalo, N. Y., read a paper on

CEREBRAL LOCALIZATION IN ITS SURGICAL RELATIONS.

The essay was devoted purely to the surgical aspects of the subject, and omitted consideration of those cases in which operation is dictated by a study of the subjective rather than of the objective features.

Cerebral topographical anatomy. — The areas which most concern the surgeon are those which cluster around the fissure of Rolando. A few bony prominences deserve attention in this connection—that at the point of the nose known as the glabella; the external occipital protuberance known also as the inion; the point of the vertex half-way between these two—the bregma; the external angle of the orbit, the tip of the mastoid process, and the lower border of the alveolar process of the upper jaw. The fissure of Rolando has its upper end about five centimetres back of the bregma, but does not run quite in the middle line; its lower end lies about half a centimetre behind the auriculo-bregmatic line, and a little above an imaginary line projected backward from the superciliary ridge; thus, the lower end of this fissure will be found about six centimetres above and a little behind the external auditory canal, or about an inch behind the bifurcation of the fissure of Sylvius. In regard to the convolutions, it must be stated that lesions of the dura mater overlying motor areas are not always to be distinguished from lesions in the cortex beneath. It is enough for the surgeon that a lesion of some kind can be located with reasonable accuracy. It matters not whether this is an old, irritative lesion, an acute suppurative process between the bone and the brain, or an abscess or tumor of the brain itself. The indication for exploration is just as strong in either case.

When and where can one trephine with safety?—The safest rule is to first apply the trephine over those areas which do not overlie large vascular channels. Afterward, the opening may be extended in any direction, and to any required extent. The greatest hesitation is with regard to opening one of the sinuses. Two dangers attend such an accident: one, fatal air embolism, the other profuse hemorrhage. The former danger is almost a theoretical one, and the other may be overcome by plugging the sinus or closing its wound with a fine needle and suture.

Cerebral and cerebellar abscess.—Bergmann has shown that abscess of the brain has but one result—death, and that the surgeon's knife offers the only relief. So far as we know, there is no such thing as idiopathic abscess of the brain; it is always the result of some external wound of the head, or some extension from diseased surrounding bone. The only exceptions to this statement are to be found in the case of pyæmia or tuberculous abscess. The symptoms of deep brain abscess may be divided into three groups, according to causes: 1. Those which are inseparable from indications of suppuration. Such are those disturbances which may follow any deep-seated foreign body. 2. Symptoms of increased intra-cranial pressure and of disturbed relations. 3. Special symptoms by which the locality of the disturbance may be ascertained so long as the gray matter is undestroyed; the collection of pus may assume large dimensions, and still no intense motor symptoms appear. Local elevation of temperature over the abscess is a symptom of importance when present, but its absence need not negative a diagnosis, if made on other grounds. Wernicke has stated that there is a peculiar disturbance of speech which points to lesion of the temporal region. This is the confusion of correct with incorrect words. In the general diagnosis of cerebral abscess, it is to be remembered that there usually is a latent period which may continue for an indefinite period. The stage of active symptoms is usually ushered in by more or less headache, slight rise in temperature; local or motor symptoms can only be expected when the abscess is in the motor area of the brain.

In operating for abscess of the brain, operators, until recently, have satisfied themselves with incising the dura and doing nothing more. With the introduction of aspirating methods, the hollow needle came to be used for brain exploration. The dangers of this procedure are certainly small. The danger of hemorrhage has been overestimated. A temporary tampon will control deep hemorrhage, while in bleeding from the pia mater the vessels may be sewed with ligatures or serre-fine. In brain-abscess consequent upon middle-ear disease, the best point to trephine, according to Bergmann, is above and behind the ear. Macewen proposes a second counter-opening on a level with the floor of the abscess.

Brain tumors.—The principal features of these growths which produce symptoms are location, size, character, rapidity and manner of growth, and extent to which they affect surrounding brain-tissue. Considered in their surgical relations, we may, with Bergmann, divide them into (*a*) the circumscribed or encapsulated, and (*b*) the infiltrated or diffuse, around which, as a rule, there is a zone of softening. A third class may be mentioned, *i.e.*, those growing from the interior of the cranium, from the bone or dura.

If a reasonably satisfactory diagnosis can be made, it must be indeed an extensive growth of the cranial vault which shall contra-indicate operation. The question of what and how many brain-tumors are operable has been best answered by White. He found, in one hundred brain-tumors met with in the dead-room of Guy's Hospital, that only nine could have been removed—one tuberculous nodule, four sarcomas, two undetermined tumors, one cyst, and one myxoma. Nine per cent. could have been attacked, providing a fairly accurate diagnosis had been made. Of these nine tumors, five were located in the cerebellum, one in the frontal lobe, and one in the extremity of the occipital. It is doubtful whether these seven could have been recognized accurately enough during life to justify operation; while the myxoma was impossible to diagnose. It is thus seen that by no means all tumors which can be diagnosed can be deemed suitable for operation.

Operation for intra-cranial tumors.—The head should be shaved two or three days before operation, washed with green soap and ether, and antiseptic compresses applied. Chloroform should be, as a rule, the anæsthetic, on account of its contracting influence on the vessels of the brain. Morphia, hypodermically, and ergot may be resorted to for the same purpose. The author suggested that after localizing the lesion, a small, disinfected, headless tack be driven through the scalp into the bone at the point determined upon. After the dissection of the external flap, this will point out accurately the point to be first attacked. In order to prevent hemorrhage, the author had found a spray of antipyrine solution (1 to 40) of service. The semilunar flap is the proper shaped one to raise. Its apex should be in such a position as to allow of drainage with the patient on his back. The periosteum should preferably be raised with the flap. The use of the trephine is preferable to the hammer and chisel. Since Macewen has taught us how to preserve the fragments of bone and restore them to their place, his method has been widely tried, and universally commended. The dura mater should be incised around a large part of the area, at a distance of one-eighth to one-fourth of an inch from the edge of the bone. The appearance of the dura is sometimes a guide to trouble beneath. In recent cases, it is sometimes highly vascular; in old cases, it may be yellowish or discolored. Wherever adherent it should be freely excised. Horsley claims that marked protrusion of the dura indicates pathological intra-cranial tension. The color of the brain should be noted, remembering that the cerebellum has normally a different appearance from the cerebrum. Sometimes, when there is uncertainty as to which convolution is the desired one, the battery may be employed. When no indication of lesion is found, further exploration may be conducted with a small aspirating needle, or a blunt probe.

Should a tumor be discovered, the incisions for its removal should be made perpendicularly to the cortex, for the purpose of avoiding hemorrhage and division of the conducting fibres. Removal of a layer of cortex, whether normal or abnormal, does not leave, as one might fear, a prominent gap with vertical sides, since in a short time the depressed portion is made to bulge almost to the level of the intact parts surrounding. In addition, the cut edges are also slightly everted, and if less brain is removed than bone, the edges are extended into the opening in the skull; thus there is a continual normal tendency to hernia, but Bergmann and others have shown that this tendency to hernia cerebri is in inverse ratio to the area of bone removed. Experience has taught that it is wise to remove brain-tissue to an extent greater than was at first considered justifiable. In all operations for epilepsy the portions of cortex nearest the evident lesion should be freely removed.

The matter of drainage must be determined according to the circumstances of the case. An abscess must be drained as long as pus is discharged. After the antiseptic removal of a tumor the cavity should seldom be drained for more than twenty-four hours. The provision for drainage may be removed on the second day, and the wound dressed with reasonable pressure over the flap. Exudation naturally collecting in this cavity, will be retained and will give rise to some pain and disturbance, but so long as the symptoms from this are not severe, the wound may be left with confidence that the fluid will be reabsorbed, and that the pressure will be the best check to protrusion.

Dangers of the operation.—The principal immediate dangers are two: hemorrhage and œdema. Hemorrhage from the pia or from the brain-substance is usually readily controlled, but disastrous hemorrhage may occur from unexpected sources. When there is bleeding a temporary tampon of iodoform gauze may be applied. The dural and skin flaps are laid over this and an absorbent dressing applied. At the end of forty-eight hours this may be removed and sutures inserted.

The second danger, that of acute brain œdema, may be brought about either by increase of intra-arterial pressure or by obstruction of the venous channels of escape. Under this accumulation the brain becomes more sodden. Removal of a portion of the cranium is virtually a diminution of the pressure normally exercised on its contents, and is often followed by reaction with production of excess of fluid.

The author had collected reports of 63 cases, which were presented in summary and in tabular form; 17 of these terminated fatally, although only 5 of these deaths could properly be attributed to the operation; 15 of the cases were abscesses, subdural or subcortical. In 11 cases the lesion was a tumor, exclusive of tubercular nodules. Of cysts, properly speaking, there were 12. The 25 other cases were of a miscellaneous nature. In 3 cases the true character of the lesion was not revealed during the operation, and was only discovered at the autopsy. In 2 cases, in which no palpable or visible lesion was discovered at the time of operating, the symptoms which led to the performance of the operation were nevertheless relieved, though nothing but careful exploration was practised.

Of the 63 operations, 17 were performed by American surgeons. Those who have themselves operated more than once are, with the number of their operations: Macewen, 12; Horsley, 11; Bergmann, 4; Weir, 3; Keen, 3; and Park, 3.

Dr. Charles K. Mills, of Philadelphia, Pa., read a paper on

CEREBRAL LOCALIZATION IN ITS PRACTICAL RELATIONS.

In his introductory remarks, the speaker referred to the fact, that from the clinical observation of practical physicians sprang the conceptions out of which developed the science and art of cerebral localization. Allusion was made to the discoveries of Bouillaud and of Broca, on speech localization; to the announcement by J. Hughlings Jackson, in 1864, that certain convolutions superintended the delicate movements of the hand which were under the immediate control of the mind; and to Hitzig's researches having originated from his observing certain ocular movements during galvanization of the heads of his patients. Brief reference was made to the history of American work in localization; to the investigations, in 1874, of the New York Society of Neurology and Electrology; to Putnam's discovery, that irritation of the white matter beneath definite cortical centres, produced movements similar to those caused by irritation of the centres themselves; to the labors of Wood and Ott on the heat centres, and to the light thrown by these investigations upon the mechanism of fever and the action of drugs upon different forms of high temperature.

Before taking up the surgical aspects of the question, the speaker briefly discussed some of the practical results wrought by cerebral localization, for psychological medicine and medical jurisprudence; for general symptomatology and diagnosis, and for medical therapeutics and technique.

Trephining for cases of insanity, particularly when guided by the rules of localization, was briefly considered. Two of the recent cases of brain operation, reported by Bennett and Gould, and by Macewen, were cited as possibly opening a new field for surgical interference in insanity; the excision of cortical areas as a method of treatment when certain subjective phenomena, such as hallucinations of sight or hearing, can be given a local habitation in the brain.

In turning to the surgical aspect of cerebral localization in its practical relations, the author stated that his remarks would be chiefly concerned with questions of diagnosis. He considered first the forms of disease and injury in which cerebral localization is a valuable aid to diagnosis; and secondly, the topographical diagnosis of the parts of the brain accessible to surgical interference, with some sources of error in such diagnosis. The forms of disease in which such diagnosis has been used are intra-cranial tumors, cysts, fractures, hemorrhages, abscesses, and discharging cortical areas.

In considering the localization of brain-tumors, Dr. Mills referred to twenty cases of autopsies occurring in his own personal experience, in about one-half of which the tumors were in surgically accessible areas, and in at least one-fourth of which successful operations might have been performed. He advocated, from this experience, the excision of old gummata, and also, in special cases, of tubercular growths. The value of localization was shown in cases of fracture, where the extent of the unseen damage could not be told by the position and character of the visible lesions.

Of the different forms of intra-cranial hemorrhage, subdural, cortical, and intra-cerebral were most amenable to localizing diagnosis. The rules for the local diagnosis of these forms of hemorrhage were then given. Dr. Mills advocated the performance of trephining in exceptional cases of hemorrhage into the ganglia and capsules—cases in which symptoms indicated that the bleeding had not broken into and inundated the ventricles. From the sections, the best site for operation in such cases, all things considered, would be in the anterior portion of the first or second temporal gyrus. He favored Hughlings Jackson's suggestion of excising localized cortical areas, even when coarse lesions could not be made out, in cases of spasm beginning locally or deliberately.

The inaccessible areas had been narrowed down by the venturesome surgical explorer, and had become reduced to the middle regions of the base and its bordering convolutions, the corpora quadrigemina, and the pons oblongata.

The characteristics of localizing symptoms were described as phenomena of irritation, destruction, instability, pressure, invasion, and reflex action. Signal symptoms and the serial order of motor phenomena were discussed. Briefly, in certain regions of the brain an accurate topographical diagnosis could be made with great certainty from positive localizing symptoms. These brain areas include the entire motor zone, in which are embraced the motor or emissive speech area, the region of Broca; the visual area in the cuneus, giving lateral hemianopsia, and the intra-cerebral visual tracts, possibly also the angular gyre and the lateral surface of the occipital lobe; in other regions of the encephalon the topographical diagnosis could be made with sufficient accuracy, even for surgical purposes, by the study of the positive symptoms, with, in addition, the application of processes of exclusion and successive differentiation. Particular stress was here laid upon the importance of pressure and invasion symptoms. These areas for approximately certain topographical diagnosis include the cerebellum, the prefrontal lobe, the temporal lobe, and even certain cranial nerve-districts, as the auditory and facial, when the lesion could be localized within the cranium between the superficial origin of the nerves and their entrance into their foramina or canals of exit.

Motor localization had become almost an exact science. The latest physiological research bearing upon the subdivision of the motor area and the light thrown upon the question by surgical operations were discussed. It was held to be imperative for the neurologist and surgeon to have exact knowledge not only of the anterior and the posterior limits, but also of horizontal subdivisions of the motor zone.

The old method of subdividing the motor zone into three elliptical or circular areas, from above downward, was considered insufficient; but the neurologist should be able to locate for the surgeon, from a study of motor phenomena, at least seven or eight positions for trephining, these positions being selected by a close study of the initial or signal symptoms, the serial order of movements, and also of the amount and character of the temporary paralysis after the seizure, and the method of extension of the persisting palsy. Reference was made to operations performed through accurate localization in these areas.

The view of Ferrier as to the localization of the centre for ocular and head movements in the second frontal gyre was concurred in, and observations were cited in its support; when turning of the head and eyes was the starting-point of the spasm this localization was probably indicated. The fact that cortical oculo-motor palsies were not present as a persistent condition, even with definite lesions of the second frontal gyre, was explained by the intimate and peculiar connections of the oculo-motor nuclei at the base; they do not persist for the same reason that paralysis in the upper distribution of the facial nerve is so seldom permanent. He believed that there was a special centre for the orbicularis palpebrarum movements, probably below and adjacent to the oculo-motor centre.

Dwelling upon the sources of error in motor localization the question of reflex spasm; of unilateral convulsions due to uræmia, lead, and other toxic agents; and to hysteria and hystero-epilepsy were briefly discussed. Sufficient diagnostic difficulties are still present to make it important, in the light of the tremendous impetus toward operation, to carefully examine all questions of differential diagnosis. In certain spasmodic affections the resemblance between those clearly of reflex origin and those as demonstrably central, was very striking. Trigeminal epilepsy, whether dural, facial, dental, nasal, pharyngeal, laryngeal, or of whatever local origin, might cause unilateral convulsions or even monospasm. Dural epilepsies are especially worthy of attention, as shown by the researches of Dupuy, Brown-Séquard, Burdon Sanderson, the New York Society of Neurology and Electrology, Duret, Roche Fontaine, and François Franck. Franck has made a careful comparison and contrast of cortical epilepsies with those which are reflex and toxic, including those which are due to irritative lesions of the dura mater.

The author referred to five cases in his own experience in which operations had been performed for epilepsies apparently reflex in character; two in which spicules of bone had been removed from the dura mater; one in which an old inflammatory lesion of the membranes and cortex, from traumatism, was present; and two in which scalp cicatrices were removed. While fearing, with Franck, that we were not always able to make a trenchant separation between reflex and cortical epilepsies, some points of separation were indicated,

True Jacksonian epilepsy, Dr. Mills believed, was sometimes reflex in origin, that is, that it was established by intense, persistent peripheral irritation, and even after the irritation had been removed the cortical discharge continued; herein perhaps lay the explanation of Jacksonian spasm without coarse lesion, and herein, also, perhaps, was to be found the justification for the excision of cortical discharging areas. The author referred to a case in which epilepsy, clearly of Jacksonian type, was just as clearly due to a fibroma involving a nerve-trunk on the palmar surface of the hand, and in which the patient was cured by removal of the growth.

With reference to sensorial localization, cutaneous and muscular, the views of Horsley and Schäfer, with reference to the limbic lobe, were accepted in part. The speaker believed that the evidence was becoming stronger every day in favor of the existence of a zone for the sensations of touch, pain, and temperature, separate from cortical motor areas. Collections of cases, such as those of Starrs, Petrina, and others, which were supposed to indicate that the sensory areas coincide largely with those of motion, were not regarded as overcoming the positive evidence of decided destructive lesions of the cortical motor zone without any sensory disturbance. From a study of his personal cases he had concluded that they did not support the doctrine that the motor and sensory areas coincide. Notes of these cases were given, and also cases from other reporters. He believed with Bechterew, that the loss of sensation in animals, who have had the motor area destroyed, was apparent and not real. Some light had been thrown upon this disputed question by careful examination of patients after operation, particularly when certain definite dural areas had been clearly excised. Reference was made to the cases of Horsley, Weir and Seguin, Lloyd and Dearer, and others. The speaker believed that these observations and experiments pointed clearly to the theory that the motor zones were motor alone in function. His view was that the region for general sensation, including touch, pain, temperature, and perhaps pressure, location, and muscular sense, could be divided into special areas for the various distinct portions of the body, and that these centres lay alongside, and had close anatomical and morphological relations with corresponding motor centres, but that they were not identical with them. He located these sensory areas in the gyrus fornicatus, the hippocampal gyre, the precuneus, and the lateral postero parietal region.

The practical conclusion was that the neurologist and surgeon must depend upon motor symptoms alone in fixing the site for operation in cases where the motor lesions were definite. When positive sensory symptoms were present, they might sometimes serve to aid in locating more exactly the position for operation, but the data were not sufficient for positive reliance.

The question of morphological peculiarities of the human brain was briefly alluded to as having some practical bearing upon the subject under discussion. The position of the so-called angular gyre and aberrations in the parieto-occipital region were more particularly discussed. Even the fissure of Sylvius, the central and parieto-occipital fissures sometimes present considerable variation; but, as a rule, such aberrations were not confusing in operating on the motor region after the methods of Broca, Thane, and others.

Dr. Mills concluded by saying that the discoveries in cerebral localization, with the achievements in antiseptic surgery, constitute the greatest triumphs which adorn the history of the noble science and art of medicine.

DR. M. ALLEN STARR, of New York City, read a paper on

CEREBRAL LOCALIZATION IN REFERENCE TO APHASIA.

It is evident from the statements just made that cerebral surgery has a great future, but is dependent on neurology for its guide. The burden of responsibility for future progress rests upon physicians, for diagnosis must precede operation. The great discoveries in cerebral localization made in the past have been reached by means of the collection and analysis of large numbers of cases of localized disease in man, rather than through physiological experiment. Future advance must be in the same line. Hence the importance, too much overlooked in this country, of recording carefully every case of cerebral disease. And to be properly recorded it must be carefully examined. This is especially necessary in the cases of disturbance of speech.

The history of aphasia presents three epochs: First, that of Broca, in which the fact was established that lesions of the third frontal convolution on the left hemisphere produced aphasia. Secondly, that of Wernick, in which a distinction between sensory and motor aphasia was drawn, and the former was shown in a few cases to be due to lesion of the first temporal convolution. Thirdly, that of Charcot, in which the four mental elements of speech were carefully separated. Charcot says, "A word is a complexus; in it we can discover, in persons of education, four distinct elements: the auditory memory-picture, by whose means we are able to grasp the sense of words heard; the visual memory-picture, which enables us to comprehend the words written or printed; and also two motor elements—the motor memory of articulation, and the motor memory of writing, the first developed by the repetition of movements of the tongue and lips necessary to pronounce a word, the second by the practice of motions of the hand and fingers necessary for writing." Each of these memories being distinct can be lost. The result is disturbance of speech whose forms vary. The loss of visual memories produces verbal amnesia and word-blindness; the loss of auditory memories causes word-deafness; the loss of motor memories of writing results in agraphia; the loss of motor memories of pronunciation produces motor aphasia. Individuals differ largely in the degree of cultivation of each of these memories, and hence suffer differently when affected by their loss; *e.g.*, the literary man presenting far more symptoms than a common laborer, when his memories of things read are lost. Another fact of importance is the independence of speech and thought. Aphasics may retain their musical faculties and may sing when they cannot talk. Thinking, though largely done by the aid of speech, is not dependent upon it. We have memory-pictures of the shape, form, or sound and odor of objects, independent of their names, and unless these are intact in the brain the perception of the object does not produce recognition of its nature or use, and does not awaken the memory of its name. The condition termed apoaxia is found, with aphasia, in some cases, but not in all.

Turning from clinical distinctions to pathology, the localization of the various memories necessary to speech was discussed. Motor aphasia is produced by lesion in Broca's centre, or in the tract from that centre to the cranial nerve-nuclei. If it is due to lesion in the latter, it is temporary and accompanied by other local symptoms. The situation of the lesion producing motor agraphia is uncertain. Word-deafness is due to lesion in the first temporal convolution, and is associated with word-blindness when the lesion extends to the supramarginal convolution and angular gyrus. All the cases of pure sensory aphasia in which the lesion was limited to these parts (forty-one in number) were collected, and a chart of the brain was shown to support the localization stated. The condition of apoaxia was shown to accompany lesions situated in or beneath the angular gyrus.

The integrity of the connecting tracts between the various memory-centres is also necessary to the act of speech. These can be tested; thus repetition after another, copying, writing at dictation, and reading aloud, are acts involving two separate areas and their connecting tract. Lesions of these tracts produce disturbances of speech, some of which Lichtheim has described. But cases have not yet been sufficiently well tested to warrant any conclusions. The necessity of careful examination of all cases, to detect various defects, was dwelt upon, and the speaker closed by indicating how readily accessible to surgical interference the speech areas of the brain are.

ASSOCIATION OF AMERICAN PHYSICIANS.

Tuesday, September 18th—First Day.

Dr. W. H. Draper, of New York, delivered the

PRESIDENT'S ADDRESS.

After a few words of introduction, in which he referred to the avowed aim of the Association, and to the honor conferred upon him in being called to preside over its deliberations, he proceeded to offer

SOME REFLECTIONS UPON THE RELATIONS WHICH SCIENTIFIC AND PRACTICAL MEDICINE BEAR TO EACH OTHER.

We may differentiate the science from the art of medicine, but we cannot practically dissociate them. In their ideal union they are interwoven like warp and woof, built into each other like foundation and superstructure. Scientific medicine, to be sure, is not always practical, but it is ever striving to become so; and practical medicine, though not always in a strict sense scientific, is constantly tending to that end. In medicine, perhaps, less than in any other department of human activity has the distinction between the art and the science been sharply drawn. In spite of this close mutual relation, the worker in the science and the worker in the art occupy essentially distinct positions, and the aim and the methods peculiar to each must be constantly kept in view. The one is a naturalist, the other an artsman. The tendency is to accentuate the distinction. The obvious results of this specializing it is hardly necessary to point out. The observations of the physician have not only suggested to the scientist some of the most interesting problems in biology but some of the most important factors in their solution. Attention was drawn to some of the disadvantages connected with the independent cultivation of the scientific and practical. Science necessarily sometimes draws premature conclusions from its premises. The only competent critic of the practical value of its theorems is the practitioner who tests them. The facts of science are of no more use as materials for practical work than the ultimate elements of our food would be for nutrition; they must first be transformed into new combinations, and then pass through a series of more or less complex changes before they can be made to yield up the force which makes them a power for good and useful achievements. The many beneficent applications of electricity, for example, have not been made by men who were eminent as physicists, but by men who were endowed with a sort of divine instinct for adapting the laws which govern this subtle force to the practical needs of humanity. How to assimilate the discoveries, how to make them all contribute to more exact diagnosis and more rational therapeutics, are the problems which lie in the path and confront the conscience and the resources of the practical physician. It is well to remember that in one sense practical is always in advance of scientific medicine, and that in another it is always in its train. It is always in advance because it is ever referring new problems to science to solve; it is in its train, because it has continually to test and digest the theorems which science suggests for their solution. There is no better illustration of this statement than that which is afforded by the history of parasitism, the latest and most portentous contribution which science has made to the theory and practice of the healing art. The germ-theory of disease may be said to have reformed surgery, but it is not safe to affirm that it may not be forging new errors in diagnosis and beguiling us into dangerous paths in therapeutics. We may well believe that we are on the eve of momentous changes in the healing art resulting from discoveries in bacteriology, but these changes must come mainly from the independent and judicious application of these new ideas to the study and treatment of disease by the practical physician at the bedside. Already the relations of bacteria to the pathology and treatment of fever furnish an illustration of the way in which clinical observation enlarges and compli cates the problem which the pathologist has to solve. Until we know how fever is produced, and whether it is a salutary or a dangerous process, to be antagonized or let alone, we are really in no better position to treat fever rationally than we were before the etiological relation of bacteria to fever was suspected. The fault of medical practitioners in the country is the failure to indoctrinate the principles and demonstrate the practice of clinical medicine, along with the purely scientific knowledge.

We must preserve science so as not to imperil the progress of art, and we must cultivate art as if science were not so much its mistress as its handmaid. We may wisely recall and apply the answer which Iphicrates, the Athenian general, is said to have made when he was hard pressed by an orator before the people to say what he was, to be so proud: "Are you a soldier, a captain, an engineer, a spy, a pioneer, a sapper, or a miner?" "No," said Iphicrates, "I am none of these, but I command them all." So the practical physician may not be a very learned pathologist, an erudite physiologist, a skilful chemist, or an expert bacteriologist, but he must command them all, and it is he who must finally, through the co-operation of all the sciences which they represent, perfect the most beneficent of all the arts; it is he who, in his high position as the servant of humanity, must attain that wisdom which results from combining knowledge with the instinct and the skill for its useful application."

DR. W. W. JOHNSTON, of Washington, read a paper entitled

GEOGRAPHICAL DISTRIBUTION OF TYPHOID FEVER IN THE UNITED STATES.

The paper was based largely upon the answers returned from three hundred and fifty physicians in various parts of the country, and colored maps showing the distribution of typhoid and of malarial fever were exhibited. Dr. Johnston's conclusions are: 1. That typhoid fever has a much wider distribution in this country than is accepted by the majority of medical men, and that its prevalence is very great in all of the regions reviewed in the paper. 2. That the varieties and modifications of type are very numerous, covering a wide range, and simulating types of malarial disease. 3. That the prevailing type is without many, sometimes without any, of the more characteristic symptoms of the disease. 4. That the principal direction in which clinical study can be useful in the present stage of our knowledge is in the collection of cases of undoubted typhoid fever; cases in which the diagnosis is made certain by characteristic symptoms, especially by post-mortem examination, in which there have been phenomena supposed to show malarial infection. 5. By the study of the localities of occurrence of such cases, by the finding of them, perhaps, in non-malarial regions, by the study of the blood and stool micro-organisms. 6. That no true progress can be made until the true value of the malaria-like symptoms are determined.

DR. STERNBERG urged the abandonment of the term "typho-malarial." In reviewing the army statistics he had noticed that "typho-malarial" fever had had a low mortality; he thought it difficult to understand how a complication could tend to diminish the severity of a disease.

DR. OSLER referred to the researches of Laveran, and their confirmation by various observers in different parts of the world, as proof that in the blood-changes we have the means of differentiating between a fever of a malarial and one of a typhoid origin.

DR. JAMES H. HUTCHINSON, of Philadelphia, read a paper on

THE MANAGEMENT OF THE STAGE OF CONVALESCENCE IN TYPHOID FEVER.

With the return of the normal temperature, the physician is prone to overlook the danger. The authorities differ greatly as to the rules laid down for the management of this stage, some advising the administration of solid food so early as the second day after the cessation of the fever; others not until a week or ten days have passed. Dr. Hutchinson favors the continued use of the milk diet with a little milk-toast, and at the end of two weeks butcher's meat. The only objection to be urged against the milk diet are the wishes of the patient and the tendency it occasionally has to produce constipation.

The administration of alcohol may be withheld in many instances; but, on the other hand, it may for the first time become necessary, and no doubt convalescence is often very much hastened by its use. Hupham's tincture he has found useful at this time, together with iron, and pepsin and muriatic acid. Severe cases should remain in a recumbent position for a week after the beginning of convalescence. At first the patient may sit up for a half-hour, the time to be gradually increased. As soon as the patient's strength will permit he should be removed to an adjacent room. Exercise in the open air is to be encouraged as soon as strength is regained. Convalescent typhoid patients are more emotional than in health, and severe relapses may occur from mental excitement. It has been noticed at the Pennsylvania Hospital that after visiting days there is more or less recrudescence of fever. The causes of recrudescence of fever and of relapses, and of some of the least known of the sequelæ of typhoid fever were also considered.

DR. PEABODY, of New York, in opening the discussion, stated that he did not believe that errors in diet were so frequently the cause of recrudescence as was formerly supposed. In regard to ulcers as a cause of diarrhœa, he is of the opinion that their presence has nothing whatever to do with its production, a conclusion derived from the frequent study of cases at the autopsy-table.

DR. ORD, of London, in a general way agreed with the reader of the paper, but thought that one cannot lay down hard and fast rules. One must be guided, in a measure, by the desires of the patient, and must give in to these desires. He referred to a hospital case which ran the usual course up to a certain period in the convalescence, when there was added a more extraordinary range of temperature for days, with delirium and an abiding desire for food. The patient had been allowed milk and beef-tea, and for ten days two eggs daily. She was given boiled sole, and within twenty-four hours her temperature was normal, and convalescence was thereafter uninterrupted. We should study the individual as well as the fever.

DR. KINNICUTT, of New York, remarked that he considered relapse to be very often a result of indiscretion in diet, and that therefore the old way of adhering strictly to a liquid diet was the best.

DR. GEORGE ROSS, of Montreal, then presented a communication entitled,

SOME FORMS OF PARALYSIS AFTER TYPHOID FEVER.

In his introduction, Dr. Ross quoted the remark of Dr. Baly, that "a book on the diseases of convalescence might be one of the most valuable that any physician could write," and stated that it was a consideration of the truth of the remark that led him to write his paper. It is an interesting question how far these sequelæ are special to certain of the acute diseases. It is not to be wondered at that the nervous system suffers after typhoid. The signs of exhaustion of the nervous system are constant, and generally in proportion to the severity of the fever. The nervous disturbance may be general, or some part of the spinal cord or some one or more of the spinal nerves exhibit altered functions. The nervous phenomena almost invariably are both motor and sensory; always in the case of spinal nerves, never in any of mixed. According to Nothnagel, the order of frequency of these affections is as follows: 1. Parts by one nerve, as the ulnar or peroneal. 2. Paraplegia, preferably of the lower extremities. 3. Less frequently, one extremity, either upper or lower, or two extremities in crossed order. 4. Simple alteration of sensibility. The history of a case of paraplegia resulting directly from typhoid fever, and ending in recovery, was given in detail, and also the history of a remarkable case which presented paralysis involving all the limbs, and, in addition, the muscles of the palate.

Dr. Ord began the discussion by stating that he had seen many cases of peripheral neuritis, and also of paraplegia and protracted cases of difficult articulation. In one case there was not only the loss of speech, but also a loss of the power of remembering words.

Dr. Minot, of Boston, thought that the sequelæ might be caused by the germ producing the original disease, or perhaps more likely by the entrance of some other germ. He referred to a case of total dumbness following typhoid.

Dr. Starr thought it a legitimate question whether the neuritis may not be due to alcohol taken either during the course of the disease or previously. Again, cases of peripheral neuritis of one or two nerves may be due to pressure in consequence of position assumed.

Dr. Delafield remarked that we have the experience that the poison of infectious disease produces, as do toxic minerals, acute degenerative processes. There is a variation as to which particular part of the body is affected.

Dr. Frederick Forcheimer, of Cincinnati, read a paper on

FATTY HEART.

The paper was based on a collection of one hundred and twenty-two cases — eighty-eight males and thirty-four females—fifty-nine of whom were below sixty years of age and forty above. The relation of obesity to fatty heart was considered, and the difficulties attending the diagnosis of the affection dwelt upon. Oertel's method of treatment was advocated.

Dr. Wood, of Philadelphia, strongly objected to the indiscrimate use of the method.

Dr. James C. Wilson, of Philadelphia, presented a communication entitled.

CAUSAL THERAPEUTICS IN INFECTIOUS DISEASES.

The paper was based upon an experimental study of the effect of hypodermic injections of calomel in the treatment of five cases of typhoid fever, all severe, and three of pulmonary tuberculosis. In all there was a distinct amelioration of symptoms, and a modification of the temperatures. The drug was given at intervals of four or five days.

Dr. Sternberg gave the results of a treatment of yellow fever that he had ventured to suggest while in Havana recently. The acidity of the contents of the stomach in this disease had led him to prescribe an alkali—bicarbonate of soda. He had received reports of thirteen cases treated by this method in Havana, and all had recovered. In regard to the constipation and the attendant rise in temperature in Dr. Wilson's case of typhoid, he stated that a species of bacillus present in the human intestine produces a fever-causing ptomaine. A rise in temperature may quite as often be produced by them as by the specific germ.

Dr. Peabody spoke of having unsuccessfully used naphtholine during the last year in the treatment of typhoid.

Dr. Jacobi extolled the bichloride treatment of diphtheria, and stated that he believes in no other way can the disease be so successfully handled.

Dr. Frank Donaldson read a paper entitled

THE DIAGNOSTIC SIGNIFICANCE OF THE PRESYSTOLIC MURMUR.

The Radical Cure of Hernia.—Dr. George W. Ridenour, of Massillon, O., writes: "Your correspondent, in his report of my paper read before the Ohio State Medical Society, June 14, gave me the credit of describing the various ways of reducing hernia. The fact is I did not mention reduction in any way, simply reporting thirty-two operations for radical cure."

AMERICAN SURGICAL ASSOCIATION.

Tuesday, September 18th—First Day.

The Association was called to order at 10 A.M. by the President, Dr. D. Hayes Agnew, of Philadelphia, Pa., who delivered the following address.

PRESIDENT'S ADDRESS: THE RELATION OF SOCIAL LIFE TO SURGICAL DISEASE.

Fellows of the American Surgical Association: As the generations fare on, enriched by the results of scientific labor, which pours its tides of opulence into all departments of human thought and industry, there follow through a reactive or reflex influence certain notable changes, not only on the life and manners of a people, but on their physical and mental diseases. The more advanced a civilization the more complex become the problems which surround it. While the accumulation of wealth and the multiplication of appliances for human comfort have in the aggregate contributed to the well-being of the race, yet there is reason to fear that the insatiate and ambitious demands of the masterful leaders in the work of the world, unless conditioned and environed by reasonable safeguards, may acquire their triumphs at the expense of human life. It is a suggestive and a solemn thought that in the victorious march of civilization thousands of victims must perish beneath her chariot wheels. There really seems to be a perpetual antagonism between man's inventions and discoveries and the well-being of a no-inconsiderable fraction of humanity. He reduces the elastic vapor of water to practical use, and is rewarded by seeing countless numbers of human beings blown into shapeless masses by his rebellious servant. His chemistry creates formidable explosives capable of dislodging the solid strata of the earth, and yet, in wicked hands, they become instruments for consummating such diabolical plots as serve to unsettle the peace of a nation. He rears manufactories for fashioning multitudinous fabrics which minister to the comfort and luxury of the race, and yet while the hands of the fabricator are busy manipulating the materials of these industries he is breathing a death-laden air. We send our missionaries to China and the Sandwich Islands to reclaim their peoples from the barbarities of heathenism, and then our commerce to ruin their souls and wreck their bodies. There seems indeed to be an eternal conflict between good and evil.

Considerations like these naturally lead to a very inviting field of study, namely, the relation between the material prosperity of a people and the forms of their disease. What I propose, however, in discharging one of the duties belonging to the honorable office to which, by your kind suffrages, I have been elected, is very briefly to follow one line of this inquiry, that is,

THE RELATION OF SOCIAL LIFE TO SURGICAL DISEASE.

There is no tyranny more exacting or despotic than that exercised by the conventionalities which govern our living. All stages of life, from infancy to old age, are under its domination. It dictates the education, the manners, the walk, the dress, the forms of speech, in fine, the whole being. Beyond all contradiction the behests of fashion are vastly more influential in governing public conduct, than any arguments drawn from the teachings of structure and function.

As a rule, when the conflict is between taste and reason, the victory will be on the side of taste. In nothing is this more forcibly displayed than in the apparel used to protect the body. It is not an agreeable task to peer into the wardrobes or dressing-rooms of our fair countrywomen. I have no special taste for exploring museums of bizarre collections. Indeed, without a key to interpret the curious and ingenious mechanisms for clothing the form divine, such an exploration would be like an archæologist attempting Egyptology ignorant of cuneiform inscriptions. I have, however, some knowledge of human anatomy in its broadest sense, and when I look upon the masterpieces of the human form, whether in marble or on canvas, a Belvidere Apollo or a Venus de Medici, and contrast these with the dressed-out specimens of modern women, I am forced to admiration; not so much at the amazing ingenuity displayed in concealing the divinely appointed form, as at the plasticity and patient submission of mortal clay under the despotism of a conventional inquisition. Were these processes of mutilation and abnormality harmless, did the body consist of a mere mass of protoplasm capable under the application of certain stimuli of assuming normally protean shapes, the subject might be passed over with the feelings of a naturalist, but this is not so. These violations of the laws of structure bring with them serious penal inflections, which, did they terminate with the original offender, might be dismissed with a sentiment of pity, but projecting as they do their baneful consequences to successors, they become proper subjects for criticism.

Let me name a few examples as illustrative of my subject. For some time the profession has been speculating on the causation of nasal and post-nasal catarrh, with its accompanying auditory defects, the growing frequency of which cannot have escaped general observation. Doubtless no single agency will explain the presence among us of this unpleasant disease, yet there are facts connected with this affection which to me are very suggestive. I cannot recall an instance in which I have met with the disease among females belonging to the Society of Friends, Dunkards, or Mennonites. If this, on more extended observation proves to be true, may not the head-dress peculiar to these people be accepted in explanation of their exemption. The bonnet which at one time overshadowed the entire head, as all know, has been gradually shrinking in its dimensions, until it has become a mere shadow of its former self, and offers no protection whatever to the head. As a substitute, I would not insist upon the quaint headgear of the Friend, though I believe that any modification which will protect this part of the body will lessen the tendency to catarrhal inflammation of the naso-pharyngeal mucous membrane.

Muscular restraint.—A legion of physical imperfections arises from muscular restraint. Among these may be mentioned weak ankles, narrow or contracted chests, round shoulders, projecting scapulæ, and lateral curvatures of the spine. The foolish concession to appearance and the unwise partiality of parents for enforced systems of education, the demands of which bear no just proportion to the capacity of the infantile mind, constitute the initial or determining force of these physical imperfections. In many cases the weak ankles of children, characterized by eversion of the feet, thus allowing the superincumbent weight of the body to be transmitted to the latter inside of the proper centre of support, is largely chargeable to the miserable practice of placing on the little ones, long before they are able to walk, boots tightly laced up the limb, some distance above the ankles. The confinement of the flexor and extensor muscles by this constriction prevents that free play of movement which reacts so favorably on all the elements of an articulation, and that, too, at a time when the growing forces are at full tide, so that, when the time arrives for standing and walking, the muscles are unequal to the firm support of the joint. The consequence of this feebleness is soon seen in the turning outward of the feet, throwing the strain on the internal, lateral ligaments, which in turn become elongated through growth, and thus the defect becomes established; but the evil does not terminate here. The calcaneo-cuboid and the astragalo-scaphoid ligaments losing the proper support of the tendon of the posterior tibial muscle, under the abnormal tension begin to yield, and to the deformity of eversion is added that of "flat-foot." That the above is not a mere hypothetical explanation of the ankle defects, I have many times verified by finding the threatening symptoms disappear after liberating the imprisoned muscles and subjecting the enfeebled parts to a judicious massage. Under no circumstance, as is too often the case, should instrumental apparatus be applied, unless in cases where, from neglect, the deformity is thoroughly established and is progressive.

Take another deformity, that of bow leg. On the earliest signs of the unsightly curve, the limb is too often trammelled with irons, and the growth of the muscles arrested, when it is well known that if manual force be systematically applied two or three times a day, the limbs will gradually assume their typical form.

Again, in further illustration of our general text, take as an example a child who, for one long or two short sessions for six days of the week, sits over the study desk, compelled to assume a position in which from the inclination of the body the shoulders fall forward, the head being supported most probably on the elbows and hands. In such a posture, the great serrati de pectoralis major and minor muscles are in a state of relaxation, while the erector spinæ and trapezei muscles are in a state of tension. This change in the position of the shoulders gives the scapulæ over, without antagonism or resistance, to the action of the rhomboidei and the levatores angulæ scapulæ muscles, which acting conjointly cause that projection of the lower angles of the shoulder-blades, which the older anatomists termed "scapulæ alatæ." To all this must be added the very important factor of four to six hours in the school-room and two hours at least of home preparation for the following day's recitations, during which time the respiratory functions having been reduced to a minimum of activity, the muscles of the chest are comparatively passive, and aeration of the blood tardy. Certainly no combination of conditions could be better devised for forming contracted chests and round shoulders. It is not long before the watchful eye of the mother detects the change in the figure of her child. She will probably discover this and take alarm, even when the pale face, the languid air, and the capricious appetite of the child cause no anxiety; and then comes the second act in the drama of physical deterioration, namely, a resort to shoulder braces and stays, in order to accomplish that which the muscles should be taught to do without restraint or encumbrance.

Lateral curvatures.—While it is true that lateral curvatures of the spine depend upon causes both central and peripheral, yet in no small number the deformity is clearly attributable to influences of a social nature. The young column, by reason of the non-union of the epiphyses and diaphyses and the supple character of its ligaments, is extremely flexible. Whatever, therefore, destroys the muscular equipose, however inconsiderable the force, if persistently repeated, changes the centre of gravity and develops primary and compensating curves. For six months in the year, any fine morning groups of young children may be seen plodding along our streets with a miniature library of books suspended from one shoulder. To the already preponderating scale of the balance, add the additional factor, a probably badly arranged light, compelling these little *savants* to assume a lateral inclination of the body in order to obtain the necessary illumination of the subjects of the study, and you have all of the conditions necessary for perpetuating the lateral deformity. "Just as the twig is bent, the tree's inclined." As in the case of round shoulders, so here in order to prop up the falling column, instrumental contrivances are immediately called into requisition. The body is encased in a formidable coat of mail, to be followed by muscular atrophy and permanent distortion of one of the otherwise most beautiful pieces of mechanism in the human frame. It is true that in most educational institutions for the young, provisions are made for physical culture, and these are in some measure antidotal to the evils complained of, but in my judgment do not at all compensate for that free unstudied romp in the open air, untramelled by the hard and fast rules of calisthenics, so fascinating to the young child. Nor does the evil end here. While the forcing process which is to stimulate the mental powers far beyond the real capacity of the immature and growing brain to receive, is in progress, another is inaugurated, which is to qualify, especially the female child, to acquit herself with distinction when the time arrives for entering the great world of society, or, as Thomas Brown would style it, "for the frivolous work of polished idleness." The gait and carriage must be reduced to prescribed rules, the voice toned down to a drawl, or trained to move like a mountain-torrent. The muscular apparatus of the face must be taught to express, not the spontaneous and natural outflow of feeling which wells up unbidden from the magic chamber of the heart, but rather to produce an effect; and so this work of transformation goes on until it culminates in the full-blown society girl. Is it any wonder that under such a scheme of education, conducted throughout by a studied disregard of both the physical and mental constitution, and exercising as it does such tremendous drafts on the nervous system, that the world is becoming filled with a class of flat-breasted, spindle-limbed young women, unfitted for the varied and responsible functions of womanhood, qualifications, too, which, under a different regimen and directed into proper channels, would exert a most potential influence on all the great social and moral problems of the age.

While thus plain spoken on the frivolous methods of living, I do not wish to be understood as being unfriendly to the highest cultivation of the mental and physical powers, if conducted on lines in harmony with the organization, nor to any technique which may conduce to personal grace or elegance of manners, so that the manly or womanly personality of the individual be not sacrificed to the Moloch of sentiment and sham. Indeed, indifference to these things is inexcusable in either man or woman, as not only lessening their influence in the world but in many respects disqualifying them for the highest discharge of the duties of modern life. Valuable as may be the unpolished diamond, yet it is only after the wheel of the lapidary has worn away the dull incrustations that its true brilliancy is revealed, and the gem is fitted to adorn the brow or the breast of beauty.

Bodily constriction.—In the further discussion of my subject, I may next notice the evils of visceral displacement and pressure consequent on abdominal constriction. Whatever may be said in regard to Greek and Roman life, the infinite care which these people displayed in developing and maintaining the very best type of the human form is worthy of admiration. The Ionic "cheton" spoken of by Attic writers and so often represented in the bronzes of Herculaneum, while it would not exactly satisfy the modern idea of dress, was at least free from the charge of interfering with the contour of the human figure. The painters and sculptors of those classic days were reverent students of nature. Their delineations were true to life. Their works furnish us with no hour-glass contractions of the human body. The constriction of the waist operates injuriously on both the supra- and infra-diaphragmatic organs. Any force acting on the base of the thorax and preventing the expansion of its walls concentrates the function of respiration, which should be general, on the apices of the lungs and hence, under these circumstances, the movements of breathing are for the most part confined to the summit of the chest. As the initial seat of tuberculosis is located at the upper part of the lungs, may not the inordinate work entailed on these parts by constriction have some part in hastening such deposits in the female where the predisposition exists? It is this forcing inward of the costal border of the thorax which causes the groove on the anterior surface of the liver, so familiar to anatomists. This pressure cannot fail to interfere with the descent of the diaphragm, and with the functions of the gall-bladder and duodenum, and exercises no small degree of influence in favoring the formation of biliary calculi, females being peculiarly prone to such concretions. The extent to which the liver may be damaged by extreme constriction of the waist is well illustrated by a case quite recently reported in the *British Medical Journal* in which a considerable portion of the left lobe of the liver had been separated from the right, the two being connected only by a band of connective tissue, and which enabled the operator to remove the detached mass without difficulty. The evil effects of this constriction on the viscera of the abdomen and pelvis are most strikingly witnessed in the embarrassed portal circulation, in the different uterine displacements, elongation of ligaments, displaced ovaries, tubal inflammations, hemorrhoids, hernia, and other morbid conditions which either prevent or disqualify the woman for the exercise of the functions of maternity, and which, in addition, through reflex influences, entail a host of functional disorders reaching into every avenue of the body and invading both the mental and moral constitution of the victim. So prolific have these infirmities become that a new department of surgery has been organized for their special management. To what, if not to social causes, can these morbid changes of structure in the pelvic organs, especially of the uterus and its appendages, be attributed? Why should laceration of the cervix uteri be so common an accident? Labor is a natural process, and ought not under ordinary circumstances to be attended by lesion of uterine tissue. I can conceive of no agency more likely to induce that muscular degeneration which predisposes to this accident than the modes and methods of modern living, especially among the inhabitants of great cities. In the expression "modern living" much is embraced. It includes culinary pharmacy, over-feeding and drinking, insufficient or injudicious exercise, improperly heated apartments, and a disproportion between the hours of exercise and rest. Contrast, if you will, the muscles of the hardy, country housewife who, bearing the cares and responsibilities of a dependent family, bustles about the livelong day in-doors and out of doors, eats with a relish her plain and simple fare, repairs at seasonable hours to bed, and sleeps the sleep of the beloved, undisturbed by dyspeptic nightmares, and, rising with the golden dawn, resumes the round of domestic toil with a clear head and supple limbs; I say, contrast this type of a class with that of another, the woman born to luxury and ease, whose capricious and exacting taste taxes the art of the professional caterer, who drags out the morning hours toying with some crazy piece of embroidery or trashy novel, lunches at one, rides out in the afternoon for an airing of two or three hours, returns to a dinner of five or six courses at seven, completes the evening at the opera, the theatre, or the assembly, and, coming home after midnight, crawls into bed weary and exhausted in body and mind, only to rise, with the best hours of the morning gone, for another day of aimless routine life. Can it be doubted that in the first case, with digestion unimpaired, with the products of textural changes consumed by functional activity and eliminated through the proper emunctories, the woman should possess vital resistance and a tone of tissue altogether superior to that of the other, whose habits of living must necessarily favor their faulty metamorphosis?

To these same agencies must be attributed that brood of nervous and hysterical evils for the relief of which the gynecologist too often, I fear, invades the domain of womanhood around which her whole sexual nature revolves, and which, save only in the direst extremity, should be sacred against all operative intrusion.

Late marriages constitute another social evil, the penal inflictions of which involve both sexes alike. Pride and luxury determine long engagements or deferred proposals. Marriage, it is believed, necessarily involves an establishment, a display, a retinue of servitors. The good old notion of two souls being united in wedlock for the purpose of being mutual helpmates and patiently together working up from modest beginnings to affluence seems to be entirely at variance with the modern idea of this relation. In the meantime the young man is betrayed into unlawful sources of gratification, alike destructive to moral and physical purity, the pollution of which incontinence is often subsequently communicated and perpetuated to wife and offspring. I would not dare to say how many cases of this nature have been entrusted to my professional confidence, though, I doubt not, my experience does not differ from that of many of my professional brethren whom I address. It is under such circumstances that many of those infective inflammations of the Fallopian tubes, as salpingitis and pyosalpinx, arise, and which entail the most serious deterioration of health.

The foot and shoe.—It may be thought by some persons that the subject of the foot and the shoe is not of sufficient dignity to appear in a public address. The Romans and the Greeks thought differently. The literature of both people is full of references to the shoe worn by both sexes. So important, indeed, are the feet to the well-being of the body that whatever impairs their usefulness, either for support or locomotion, becomes a positive calamity. Nothing can be more unlike the human foot than the modern shoe. Let anyone leave the impress of his or her foot in the wet sand of the sea-shore, and then place alongside of the imprint a fashionable shoe; that the two were ever intended for each other would scarcely strike a child of the forests. The North American Indian entertains juster notions about clothing this portion of his body than does the civilized denizen of New York or Philadelphia. Compare the moccasin with the shoe of the city belle. Compare the *βανδαιον* or the *πεσδικά* of Pollux and of Aristophanes with the same, and we shall see that the savage and the polished Greek alike understood the value of sound feet in the race of life. It is the imperfect adaptation of the shoe to the foot which constitutes the fruitful source of tired ankles, corns, bunions, overlapping of the toes, and ingrowing nails. Some idea may be formed of the magnitude of the evil from the fact that of eight hundred patients under the care of a prominent chiropodist of Philadelphia, the great majority of the defects were entirely attributable to the high heels and the contracted toes of the shoes. Especially do these physical encumbrances, arising from a blind submission to social laws, operate disadvantageously to our fast women at the beginning of the new dispensation requiring both muscles and brains, and when her friends propose to sweep away all the old traditions and claim for her the earth with all its masculine employments.

Games and amusements which in themselves are proper and praiseworthy, too often become developed into a craze, working both moral and physical mischief. Professor Lauf, himself a professional in the national game of base-ball, has described the pitcher's arm, a condition of over-taxed function, and one in which all the anatomical elements of the upper arm are involved. There is also the tennis arm and the swollen, supersensitive prostate of the bicyclist, both due to the abuse of popular amusements.

Defects of refraction or visual defects constitute another class of affections fairly attributable in many instances to social influences. The number of children who may be seen in our streets any day wearing glasses has become a matter of common observation. It is far from being probable that the most exquisite piece of mechanism, the human eye, came from the Divine Artificer imperfect. Because eyes are young, it does not follow that they are thereby better fitted to sustain prolonged use. Just the reverse is true, and it is high time that parents and educators begin to recognize the fact. The power of the eyes for continued use, like that of other organs of the body, is one of gradation. It moves in the general procession and strengthens with the advance in life, until development has attained to its zenith. Not only so, but the eye being a part of the body, it must suffer or rejoice through the operation of general causes. A bone may have its normal curves changed, a tendon may slip from its appointed groove, or a blood-vessel be destroyed, and yet very little disability be realized; but the eye is made up of such extremely delicate structures and acts according to fixed physical laws, that not the slightest alteration of a curve or the mobility or density of its media can occur without great vitiation of function. To exact, therefore, long hours of study from children of a tender age, involves a degree of functional strain altogether disproportionate to the structural resources of the organ, and by disturbing the orderly processes of nutrition gives rise to hypermetropia, asthenopia, astigmatism and its companion, headache. To prove that the picture is not too highly colored or the causation overstrained, we have only to contrast the children born and reared in those portions of the country not too much dominated by the methods of modern civilization, and who rarely demand a resort to artificial aids to provide for abnormalities of vision. The only remedy for the evil, where infantile scholarship is insisted upon, is the Kindergarten or object system, the most natural and effective plan of impressing the young mind.

Renal disease.—Is there any reasonable explanation drawn from sources of a sound nature for the great frequency of those renal disorders which come more particularly under the care of the surgeon, as crystalline deposits and calculi? For maintaining the general health at the highest physiological standard, a proper quality of food and the proper disposal of tissue-waste are essential conditions. Along with wealth and luxury come the abuses of the table. Americans are fast becoming a nation of dyspeptics. Our country is so rich in the products of every zone, that nowhere else in the world can you find such a variety of foods, animal and vegetable. These foods, manipulated in a thousand ways by the subtle art of the professional cook, almost necessarily betray one into excess, and also create the desire for wines and other alcoholic beverages to aid the stomach in disposing of its plethoric supply. In great cities, which furnish relatively the largest number of cases of renal disease—affecting preeminently the mercantile and sedentary classes—we find just the conditions favorable to their development. The competition of trade keeps the merchant always at white heat. Time is golden and the street-car and other means of conveyance annihilate distance, and the ride is substituted for the needful walk. A hasty lunch at the most convenient restaurant satisfies the inner man until the business of the day is closed, when, weary and worn, he is driven to his home to partake of a course dinner, the balance of the evening to be spent on the lounge with the evening paper or the latest periodical. To the literary man the fascinations of the study and the library charm him away with their siren voices from the fields and the highways, until bodily exercise grows distasteful and repugnant. In the mean time there has been no provision made for the waste or tissue metamorphoses of the body through that great agency, exercise. This tissue-waste accumulates in the blood; the internal eliminating organs, of which the kidneys are chief, are overtaxed, and then follow the evils of malassimilation, and of excretion, in the form of urates and oxalates, often resulting in the formation of calculi.

In conclusion, may we ever hope for a time when the race will realize that these bodies which we wear, which God has so highly honored by his own incarnation, are sacred temples to be kept in harmony with recognized physical laws, and not to be made instruments of mere animal gratification?

DR. JOHN ASHHURST, of Philadelphia, read a paper entitled

A CONTRIBUTION TO THE STUDY OF EXCISIONS OF THE LARGER JOINTS.

The remarks are based upon the records of one hundred and twenty cases, in my own practice, in which excision of the larger joints have been required, and will refer particularly to the operative method, the after-treatment, and the functional value and limitations of applicability of excision in the case of each articulation. The one hundred and twenty cases embrace four of shoulder-joint; nineteen of elbow-joint; forty of hip-joint; fifty-one of knee-joint, and six of ankle-joint excision.

Shoulder-joint.—My four shoulder-joint excisions have all terminated successfully. They all occurred in adults, three times in young persons, and once in an old person.

In excising the shoulder-joint, or, more strictly speaking, the head of the humerus—for the glenoid cavity rarely requires more than superficial scraping or gouging—I have employed the method by a single longitudinal incision; when the parts are matted together by long-standing inflammation, the tendon is difficult to recognize and not seen until it has been severed.

In the after-treatment I attach much importance to the use of the well-known cushion devised by Professor Stromeyer. It keeps the elbow out from the trunk, thus insuring the close application of the sawn humeral shaft to the glenoid cavity, and enables the patient to sit up or lie down at pleasure, without disturbing the dressings.

The functional utility of the limb after excision of the shoulder-joint is, upon the whole, quite good.

Elbow-joint.—Of the nineteen cases of excision of the elbow-joint, six have terminated fatally; two adults died within five days from traumatic gangrene following injuries so severe that amputation would have been the better operation. One died of delirium tremens; two from tubercular meningitis; and one, an old man, from exhaustion in the course of the fifth week.

In excising the elbow-joint I employ a longitudinal incision on the inner side of the articulation, taking care not to wound the ulnar nerve and to retain the attachment of the biceps. As a rule, all the articulating surfaces should be removed, and, within reasonable limits, the more bone that is taken away the better. since flail-like union is less to be dreaded than anchylosis.

Hip-joint.—I have forty times resorted to excision of the hip-joint in thirty-seven patients. Twice have I excised, at intervals. both hip-joints in the same individual, and once have I had recourse to re excision in a case in which recurrent caries and recontraction followed some months after the patient left the hospital. This case terminated fatally from suppurative osteo-myelitis and septic peritonitis at the end of a fortnight. Both cases of double excision did well. Of the forty operations, twenty-eight have been followed by recovery, eleven by death, and one is still under treatment. Of the thirty-seven patients, twenty-five have recovered and eleven died. Should the patient now under observation die, the mortality-rate will be, as regards operations, thirty per cent.; as regards individual patients, 32.4 per cent., a much better showing than the results given by most statistical writers.

The incision employed begins with a straight cut in the direction of the fibres of the gluteal muscle, curves around and behind the trochanter, and terminates again in a straight cut corresponding to the axis of the femur. While affording free exposure to the joint it necessitates but little transverse division of muscular fibres. The head of the bone may be made to protrude and may be removed with the chain-saw, or, under other circumstances, divided by a small saw *in situ*. It is my custom to remove both trochanters and round off the sawn end of the femur.

The functional result of hip-joint excision must be somewhat differently judged from that of excision in the case of other articulations. In most instances the operation is performed only when death seems threatened by profuse suppuration or its consequences, and if the patient is relieved of pain and restored to a fair state of health and comfort the treatment is amply justified. At the Children's Hospital, in Philadelphia, where twenty of the forty operations were performed, the rule is not to operate except in otherwise hopeless cases, and hence our recoveries represent as many lives saved; but, in many cases, excision not only saves life but restores the patient to the active duties of existence. In thirteen of the twenty-eight cases the patient obtained a useful limb, and in two of these the utility is qualified as perfect. The condition which most often calls for this operation is hip disease. I consider the operation suitable in certain cases of gunshot injury. For uncomplicated anchylosis it is not to be recommended, simple osteotomy being here a safer and surer method. Where anchylosis coexists with extensive caries or necrosis, excision may properly be resorted to. I am afraid that the "age limit" for hip-joint excision must still be maintained; in the case of the knee I have ventured to extend the benefits of this conservative procedure to adults, and even to middle-aged persons, and with great success; but excision of the hip-joint becomes an operation of great and rapidly increasing gravity when once puberty is passed. Thus, while I count twenty-five successes and only four deaths in persons under fifteen years of age, I have had only three recoveries and no less than seven deaths in those older. In adults the operation should only be undertaken with a clear understanding of the very great risks by which, under these circumstances, it is attended.

Knee-joint.—I have performed fifty-one excisions in fifty patients, once having employed re-excision for anchylosis with recurrent deformity, in a case in which I had excised the joint nine years before. Once I amputated the thigh, ten weeks after excision, on account of the beginning of failure of health, and a good recovery followed. Of the fifty-one cases but five have ended fatally, a death-rate of less than ten per cent.

In excising the knee-joint I have uniformly adopted the single transverse incision, and have invariably removed the patella. The bone sections are commonly made with a butcher's or bow saw. I take particular care to remove all of the diseased synovial membrane as well as all patches of carious bone. In treating the large bursa beneath the quadriceps muscle, I have endeavored to hasten the cure by making a long incision on the outer side of the limb, and either dissecting the bursa out bodily, or else scraping away its lining membrane with a sharp curette.

The utility of the limb, after successful excision of the knee, is very great. The limb is stiff and slightly shortened, the foot is sometimes a little inverted, but the limb is strong, painless, and enduring, and enables the patient to lead an active, useful life. As a substitute for amputation—and it is as such that I employ it—the merits of knee-joint excision cannot be gainsaid.

The cases in which excision of the knee-joint is indicated are chiefly those of arthritis—particularly of the variety for which years ago I suggested the name gelatinous—of caries, of neglected epiphysitis, etc. The operation may properly be performed in anchylosis with deformity, and also in certain instances of wound of the articulation where the extent of the injury is limited. In most traumatic cases, however, I believe that when any operation is called for, amputation will be found preferable.

Ankle-joint.—I have resorted to this operation six times, although about as often, I have removed the astragalus without interference with the tibia and fibula. Two of the six cases proved fatal from phthisis, one four months, and the other nine months after operation. My impression is that this operation in itself is attended with very little risk.

In excising the ankle-joint I make an external incision curving around, behind, and below the outer malleolus, and carried forward as far as can be done without endangering the extensor tendons, and prolonged upward as far as needful in the line of the fibula. A second smaller incision is made longitudinally over the lower end of the tibia. It is usually desirable to remove the whole astragalus. This is perhaps the most tedious and difficult of all excisions, and the operation may be facilitated by rendering the part bloodless by the use of the Esmarch apparatus. The ankle-joint is the only joint, with the exception of the wrist, in the excision of which the use of this apparatus seems to me to be desirable.

The large majority of my excisions have been performed without any of the so-called "antiseptic precautions," and the wounds have been dressed with simple oiled lint, or with lint saturated with dilute alcohol. For more than a year past, however, I have employed the antiseptic method in almost all my large operations, using also antiseptic dressings in their after-treatment, and I think with benefit; though I am obliged to say that, as regards the ultimate welfare of the patients, I have not noticed any gain. My best series of consecutive successes have been obtained under old methods, and I have not obtained any diminution of mortality by the adoption of the new. At the same time I have seen no ill results which could be attributed to the use of antiseptic measures; their use shortens the period of convalescence, and they have the merit, on account of the infrequent change of dressings needed, that they greatly lessen the surgeon's labor. I know of no cases which require more personal and unremitting attention than those of excision, and it is an unquestionable advantage to be obliged to dress a wound only once a week, or every other week, instead of daily or every other day.

What will be the future of the operation of articular excision? The brightest triumph of conservative surgery, in the hands of Fergusson and his successors, will it keep its place? or, as some of our more enthusiastic brothers prophesy, well-improved methods of dealing with joint disease in its early stages make excision a matter only of surgical history and of antiquarian investigation? It seems to me that, as the introduction of excision did not enable surgeons to abandon amputation for articular lesions, so, improve treatment as we may, and educate the public as we may as to the necessity of being treated early, there will always remain a class of cases in which only by sacrificing a part can we hope to save the whole, and in which excisions of the larger joints will therefore still be resorted to by judicious and conservative practitioners.

Dr. Lewis A. Sayre, of New York: The paper of Dr. Ashhurst has so thoroughly covered the ground that very little is left to discuss. In excision of the hip-joint I have been in the habit of using the wire curve, for the reason that it permits the carrying of the patient into the open air, an object not readily attained when the patient is kept in bed with the ordinary apparatus.

In regard to the antiseptic treatment, which I practise entirely, I think that I may claim that I have used it without knowing it, from the time that I commenced the practice of surgery. I think that my success has been largely due to the practice of pouring into the wound Peruvian balsam, which, from the creasote it contains, is an excellent antiseptic. I have also always arranged for thorough drainage. When I practised my first excision, in 1854, the operation was universally condemned. Some now seem to be going to the other extreme and performing excision of the hip-joint too early, before a thorough trial of local and general treatment has been employed.

Dr. R. A. Kinloch, of Charleston: There is now no disagreement so far as the general question of excision is concerned, but there are still some important questions to be considered. In the first place, the distinction of traumatic from pathological cases amenable to operative procedure, and in the next place as regards the joints which are apt to do best in connection with excision for traumatism and for pathological processes. A consideration of the age and surroundings of the patient is of importance. Probably the best results follow excision in connection with shoulder-joint excision for traumatism. In connection with gelatinous inflammation of the elbow-joint, I have had satisfactory results even where all the material could not be removed. I feel sure that if a few of the principles of so-called antiseptic treatment—cleanliness, thorough drainage, and absolute rest—are adopted, many of the details may be omitted.

Dr. T. F. Prewitt, of St. Louis, insisted on the necessity of getting cases of excision in broken-down children out of doors as soon as possible.

Dr. F. S. Dennis, of New York, called attention to cases of excision of knee-joint for disease beginning in abscess in the condyle. In these cases the abscess-cavity breaks down after recovery, leading to the production of deformity. In these cases he takes away all of the abscess-cavity, saws away a corresponding piece from the tibia, and brings the oblique surfaces together. He employs antiseptic dressings, removing the drainage tubes on the third day, and allowing the first dressing to remain five or six weeks. In excision for injury, only enough bone to allow of free drainage should be removed.

Sir William MacCormac, of London, said he had heard with some surprise that the tendency seemed to be to postpone excision of the hip-joint until all other measures had failed. This is not the practice in regard to any other joint. In England, the disposition is to perform the operation at an earlier period. Another point that he had not heard mentioned in the paper was in reference to the performance of the operation in cases of old dislocation of the joint. He had performed this operation with success in all hip-joint dislocations, and reported the case of a sailor coming under observation three years after the occurrence of dislocation of the hip-joint, which had not been reduced. After the operation he could use the limb perfectly. He had been much interested in the recommendation of Dr. Ashhurst, that a long incision be made to reach the subcrural bursa, a suggestion which he had not heard mentioned by any other surgeon.

Dr. E. M. Moore, of Rochester, had been somewhat surprised to hear a certain amount of indifference expressed toward the use of antiseptic surgery. He had found in his practice the greatest improvement follow the use of antiseptic dressing in these cases of excision. He cited several cases, showing the result obtained.

Dr. John E. Owens, of Chicago, said he agreed as to the value of the wire cuirass, and referred to a modification of this apparatus, consisting in a substitution of a frame of gas-pipe conforming to the outline of the body. On this the body is supported by means of flannel stretched between the two sides of the frame. Extension may be applied if desired, by the use of adhesive plaster, counter-extension being provided for by elevating the foot of the frame. After keeping the patients in bed for thirty days, he tries to get them into the open air. He had found great advantage in keeping up a certain amount of extension after the patient was allowed to get up. By removing pain, this enables the patient to move the joint more freely, and thus tends to favor greater mobility of the part. He thought that there was no comparison between the antiseptic methods and those formerly employed.

Dr. Frederick Lange, of New York, referred to a class of cases in which the disease of the hip began in the tissue outside of the joint, the articulation becoming involved at a later stage of the affection. In these cases he recommended early operation, with the hope that in this way necessity for opening the joint would be avoided.

AFTERNOON SESSION.

Dr. Nicholas Senn, of Milwaukee, read a paper on

THE RELATION OF MICRO-ORGANISMS TO INJURIES AND SURGICAL DISEASES.

The paper was so extensive that in the limited time allotted to its consideration, the author was able to refer to but a few of the points which it contained. At the present time no argument is required to show that many special conditions are due to the presence of bacteria. In regard to the so-called hereditary transmission of disease, the author held that the specific microbes of the specific diseases are transmitted directly from parent to child. In evidence of this, he referred to cases of so-called hereditary osteo-myelitis in newly-born infants. In other cases, while this same origin may be inferred, we have as yet no direct evidence that such is the case. In regard to the question whether or not pathogenic micro-organisms exist in the healthy body, while the results of some observers point in this direction, the results of others are opposed to the existence of pathogenic organisms in the healthy body. The conclusion was that, under certain circumstances, pathogenic organisms might be present. There is proof of this in cases in which, after accidental injury, there is localization of these pathogenic organisms. Acute suppurative infectious osteo-myelitis, following slight injury or exposure, was cited as an illustration of this fact. This localization is favored by certain anatomical conditions. The antagonism among micro-organisms was being considered, when the allotted time of the author expired.

Dr. Roswell Park, of Buffalo, had done some work in this direction. He had examined pus from fifty-two sources, and presented a table showing the number of cases in which pyogenic bacteria were found.

He had also prepared culture-media with various antiseptics in different proportions, including carbolic acid, iodoform, iodine, naphtholine, hydro-naphthol, resorcin, trichlor phenol, creolin, sulpho-carbolate of soda, boric acid, perchloride of iron, antipyrine, antifebrin, and quinine. Almost the only one of these antiseptic jellies, as thus prepared, which has prevented all growths was hydro-naphthol, 1 : 100. This shows that hydro-naphthol can be relied upon as antiseptic. Many of the bacteria grow freely on iodoform jelly, 1 : 100. Those which grew abundantly on iodoform jelly grew slightly on oxide of zinc jelly, 1 : 100. Oxide of zinc was considered a better solid antiseptic than iodoform. The author thought that our present knowledge permitted us to associate certain bacterial forms with definite pathological lesions. In conclusion, he presented the report of a case of abscess of the face in which he found the micrococcus tetragens. So far as he knew, this micro-organism had never before been found in phlegmon in man.

Dr. William H. Carmalt, of New Haven, remarked that there was only one point to which he wished to refer; that was in reference to the alleged microbic origin of tumors. A great deal has been said in regard to the microbic origin of cancers and other tumors. He thought that the division of Virchow's class of granulomas into a class of tumors by themselves, known as infectious tumors, is correct. This class includes tubercle, syphilomes, lepra, lupus, actinomycosis, and myelitis. These growths should be taken out of the class of tumors and assigned to a class by themselves. He had been unable to convince himself that tumors proper have a bacteriological origin.

Dr. Senn, in concluding the discussion, said that the diseases enumerated in his paper included only those in which the specific cause had been isolated, cultivated outside of the human body, and in which the injection of this culture produces identical lesions. When these three things are done, we have furnished positive proof that the disease is due to specific germs. Another class of diseases had been alluded to in the paper, in which there was reason to believe, from analogy, that the affection was due to specific germs, although the three conditions above referred to had not as yet been fulfilled. So far no one had been able to show that the supposed bacillus of syphilis was the specific bacillus. That it is a specific disease cannot be doubted; that it is due to a microbe cannot be doubted, but to establish this positively, experimenters must do what Koch did before he announced the specific origin of tuberculosis. He was finally convinced, from his observations, that tumors, in the true sense of the word, were not due to microbes. He had made tumor-implantations for many years in animals, and in justifiable cases in man, both close to the original seat of disease and at remote points, without obtaining the least evidence of the microbic origin of disease.

Dr. W. W. Keen, of Philadelphia, then read a paper entitled

THREE CASES OF BRAIN SURGERY.

The first case was one of removal of a large tumor from the brain, the second trephining for old depressed fracture followed by epilepsy, with removal of underlying brain-substance. The third was the removal of the cerebral motor centre for the left wrist and hand for epilepsy. The three patients were presented.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Tuesday, September 18th—First Day.

Dr. McArdle, of Washington, made a very happy

ADDRESS OF WELCOME,

during the course of which he pointed out the importance of this meeting.

Dr. William H. Taylor, of Cincinnati, delivered the

PRESIDENT'S ADDRESS.

He acknowledged the high honor he had received, and appreciated the responsibility accompanying the same. As a reason for the existence of the Society, he said that every man who saw in his profession something more than pecuniary profit must have a desire to know the unknown. The united effort of the many is more fruitful than the inharmonious working of individuals; hence the propriety of co-operation, *i.e.*, organization. It may be admitted that the motive of our Association is our own advancement, yet this will bring good to the profession at large, and through them to their clients. The activity of the present decade has given us a new gynecology, and words cannot describe the advances thus made. Never before in the history of the profession have the auguries been so auspicious for the accomplishment of the purposes set before us, as evinced by the cosmopolitan harmony and close association of our profession in all parts of the world, in the facilities for the speedy transmission of every item of interest, of every discovery and every suggestion, and, more important than all else, by the number of devoted workers who, animated by no unworthy craving for worldly honor or love of gain, are delving into the mysteries of the human frame, scrutinizing every group of asserted facts, and counting the few precious stones of truth which are found abundant pay for the toil.

The proper indication for abdominal section, the true position which electricity shall occupy in gynecology, the propriety of hysterectomy, the value of Alexander's operation and its newly devised congener, abdominal fixation for retrodeviation of the uterus, the relative merits of craniotomy, Cæsarean section and induced labor, the best method of dealing with extra-uterine pregnancy, the proper means of securing antisepsis, are all questions fraught with great interest, and merit the most thorough study. Leaving the most important subjects which would come up before the body for discussion, he called their attention to those smaller items which, in the daily routine with most of us, demand our thought, and if they contribute to the welfare of those in our care, are not too trivial for our study.

LAPAROTOMY IS DONE TOO OFTEN,

he said, and with insufficient grounds for so serious a procedure, but this is no reason why the operation should be condemned. Through all history all great advances have had unworthy advocates. Vaccination, anæsthesia, and ovariotomy have been subjected to great animadversions and misinterpretation, and have prevailed. Thus shall it be with laparotomy.

Statisticians and social scientists see in the decreasing fecundity of American women clear evidence of the truth of the charge that intentional abortion is a common crime, but the speaker did not believe that it is so universal an evil. A more demonstrable cause of diminishing fertility was to be found in the social habits and the fashionable education which incapacitate, in whole or in part, the power of completing the process of maternity. We see the rich, who are incapacitated in this way, bearing but few children, while their poorer sisters, who cannot have this education and social habit, are bearing their full share.

A subject demanding careful attention is the inability of mothers to nurse their children. The number of such defective mothers reaches the enormous per cent. of forty with us; much of this is due to faulty methods of dress and life.

TO MITIGATE THE PAINS OF LABOR

is a most worthy consideration, and should receive our attention. Many use chloral early and anæsthetics late in the progress of labor. Many, however, do little to lessen these pains. We should surely be able to divest this ordeal of the intensity of its pain. The speaker said that he hoped, by another meeting, to be able to report on some experiments in this direction.

The beneficent result of comparative study of a given subject is remarkably demonstrated in the case of Cæsarean section, upon which have been grafted so many modifications, nearly all of which have been submitted to the criticism of practical experience and have been cast aside as harmful or at least needless. With this and other examples, no further argument is required to establish the value of a carefully devised system of case-taking and reporting under our supervision.

Grand as has been the success of our profession, we are not to rest here. We can realize the instability of much that cost us great toil. Doctrines and practices in favor at this Congress may be modified or superseded at the next. The lapse of five years takes the bloom off the best text-books, and in ten years they are discarded or have to be wellnigh rewritten. Science knows no sentiment, and we can cherish the achievements of the past only so far as they aid us for the future. Almost every day brings new surprises; so we may confidently anticipate advances and successes which shall as far surpass our present attainments as these do those of the past generation, and happy may we count ourselves that this Association, so auspiciously established, shall contribute to these magnificent and beneficent attainments.

Letters of regret were read from Drs. Harrison, of Liverpool; Apostoli, of Paris; and Pean, of Paris.

Dr. Cordez, of Geneva, read a paper on

ENDOMETRITIS TREATED BY INJECTIONS OF STRONG NITRIC ACID.

He used one gramme in one case; four grammes in another; and four grammes in a third. In order to prevent burning of the vagina he fills the latter with a saturated solution of bicarbonate of soda. The after-treatment consisted of intra-uterine and vaginal douches of weak sublimate solution. Two cases resulted in cure, and one in failure.

Dr. Cordez also read a paper on

PUERPERAL ECLAMPSIA,

in which he advocated bromides and chloral.

Dr. Lapthorn Smith, of Montreal, advocated strongly the immediate induction of premature labor so as to take the pressure off the renal veins, which causes uræmia, which in turn causes the damage to the brain. As soon as we know that the urine is loaded with albumen, he thought that further delay was dangerous. We ought not to wait until the last, when even a breath of air would bring on a convulsion, but start at the beginning, when interference was without danger.

Dr. Clarke, of Cambridge, asked if it was not dangerous to interfere on account of bringing on convulsions.

Dr. Smith replied that with antiseptic precautions it was safe, if done early.

Dr. Price, of Philadelphia, advocated the induction of premature labor after careful preparation with a hydragogue cathartic. He cited several cases where he had thus saved mother and child.

Dr. Potter, of Buffalo, argued in favor of the induction of premature labor, and cited a recent case where the mother and child were saved.

Dr. Clarke, also cited a case where mother and child had been saved by inducing premature labor.

The Chairman explained that Mr. Lawson Tait was suffering from domestic affliction which prevented him from attending.

Dr. J. Price, of Philadelphia, read a paper on

DRAINAGE IN ABDOMINAL AND PELVIC SURGERY.

He said it was better to leave in a drainage-tube in every case, even when there at first appeared no necessity for it; for sometimes after the operation there is an effusion of blood greater in extent than the peritoneum can absorb. He preferred to fill the tube with antiseptic cotton which should be frequently changed. He advocated syringing the abdominal cavity frequently with water through the tube. He deprecated antiseptics in the abdominal cavity, which always cause pain and adhesions. He could not see the advantage of draining through the pelvis.

Dr. Clinton Cushing, of San Francisco, presented a communication on

THE STUDY OF PELVIC ABSCESS.

The most common cause is pyosalpynx, as held by Lawson Tait; or even the forcing of catarrhal secretion out of the distant end of the Fallopian tube into the peritoneal cavity. He cited several cases where it had been undiagnosed for years, and where on opening the abdomen he had found large abscesses. Symptoms: Fever, emaciation, rigors, and night-sweats. The aspirator will often make the diagnosis certain. Prognosis is good, provided it is not tubercular. The pus must be evacuated and the abscess-cavity kept clean. In pyosalpynx the abdomen must be opened. In abscesses of another nature the abscess may be evacuated through the roof of the vagina. He exhibited a dilating trocar, resembling a uterine dilator with a sharp point, to be used in cases where there would be danger of wounding an artery.

Dr. Potter exhibited a drainage-tube with a retaining collar.

Dr. Eastman, of Indianapolis, advocated using a rather large tube, as the pus is sometimes very thick. Bozeman dressing forceps, sharpened, answer admirably for introducing the tube. He followed the old plan of leaving the ends of the ligatures hanging out of the wound. He did not think that permanent drainage was possible. He has done away with ventral hernia by care in adapting the sides of the linea alba.

Dr. Montgomery, of Philadelphia, did not agree with Dr. Price in advocating drainage-tubes in all cases. The necessity for them depends greatly on the condition of the patient. Diminishing the diet helps absorption; and tight bandaging lessens venous oozing. He recommended putting a rubber apron over the dressings with a small slit for the tube to pass through. In some cases he was strongly in favor of vaginal drainage.

Dr. Marcy, of Boston, thought that the drainage-tube often failed to protect the patient. He had not used one for two years, because he has not had a case in which he had not succeeded in making the peritoneum aseptic. When he did use one he would certainly drain through the vagina. His own drainage-tube is a return flow.

Dr. Clarke, of Cambridge, also advocated vaginal drainage.

Dr. Vander Veer also advocated the vaginal drainage; he said that the late Dr. Peaslee owed a great deal of his remarkable success to vaginal drainage. He favored the view of Dr. Eastman regarding the avoiding of hernia.

Dr. Price said that Dr. Cushing's paper was well worth carrying across the continent. He referred to Cæsarean section as the now natural method of delivery. He advocated three or four sutures to the inch, but not tight ones, and to take in twice as much fascia as of skin. He was opposed to aspiration because these troubles are multiple. Even his nurses preferred to nurse a drainage-tube case.

Dr. Montgomery, of Philadelphia, read a paper on

LAPAROTOMY IN PERITONITIS.

He advocated this as the only justifiable treatment in the puerperal form, and especially in peritonitis after perforation of intestine; it is almost sure to be followed by the recovery of the patient. In tubercular peritonitis it is especially successful. Seeing that the only alternative is death he thinks the operation should in all cases be tried.

Dr. Rickett was very emphatic in his approval of this method of treatment. He thought it especially desirable to have the general practitioner recognize the disease early.

Dr. Opie, of Baltimore, also favored the operation in these cases.

Dr. Vander Veer, of Albany, read a paper on

THE RELATION OF THE ABDOMINAL SURGEON TO THE OBSTETRICIAN AND GYNECOLOGIST.

He eulogized specialism, but he held that the best specialists were those who had for many years been general practitioners. He thought that abdominal surgery should be a specialty of its own. He thought that obstetrics had made greater progress in America than in any other country. He advocated resorting to abdominal surgery in cases where formerly craniotomy was employed. He thought that abdominal surgeons, gynecologists, and obstetricians should work hand in hand.

Dr. Gordon, of Maine, said he was now making abdominal sections under the worst sanitary conditions, when they were unavoidable. and with just as good results as though they were done in special hospitals.

Dr. Wathen, of Louisville, read a paper on the

SURGICAL TREATMENT OF THE PERINEUM,

in which he pointed out that it was not the laceration of the skin or mucous membrane which caused the symptoms, it was the separation of the pelvic fascia and the perineal muscles which required to be remedied. He was afraid to use successive layers of buried sutures, after the manner of Martin, because he was not sure of the catgut, and lest the sutures might strangulate the tissues. He did not approve of removing any flap, even when it was redundant. He recommended surgical cleanliness, but not antiseptics.

Dr. Marcy, of Boston, read a paper on the

FEMALE PERINEUM; ITS ANATOMY. PHYSIOLOGICAL FUNCTIONS AND METHODS OF RESTORATION AFTER INJURY.

The paper was illustrated with oxyhydrogen light and screen. The speaker pointed out the points of resemblance between the male and female perineum. He called attention to the function of the vaginal column in fixing the cervix backward while the rest of the uterus floated free by its ligaments. He strongly urged the immediate operation with the fingers in the rectum, and by the aid of cocaine injections. He then reviewed the methods of various operators, and showed that some of them were satisfied with union of the mucous membrane only. The reader showed that he was the first to use buried animal sutures.

AMERICAN GYNECOLOGICAL SOCIETY.

Tuesday, September 18th—First Day.

The address of welcome was a few well-chosen words by Dr. S. C. Busey, of Washington, Chairman of the Committee of Arrangements.

Dr. Busey moved, and Dr. Barker seconded, the suspension of the rules. Passed. Dr. Barker then moved to reconsider the vote of last fall which decided for the Society not to unite with the Congress, and moved that they now do

UNITE WITH THE CONGRESS.

which motion was carried unanimously.

Dr. Busey then moved that the Chair appoint a member of the Executive Committee for the Congress from this Society. This motion then prevailed, and the Chair appointed Dr. Fordyce Barker as member of this committee.

Dr. Howard A. Kelley, of Philadelphia, then read a paper on

PALPATION OF THE URETERS IN THE FEMALE.

This, he thought, was a new and valuable adjuvant in the treatment and diagnosis of diseases of the ureters and kidneys. Calcareous masses resting in the ureters or in the kidneys could be readily determined. Inflammatory conditions could also be made out. Gynecology has opened up to it a whole new realm by this method of studying the ureters. The ureters, he said, could be examined by inspection or by palpation. Free-handed catheterization of the ureters after the method of Professor Karl Pawlick, of Prague, was his favorite method. Pawlick only dilates the bladder with some bland fluid as a preparation. The doctor then went on to give this method in detail. Only yesterday morning he had catheterized a male's ureters without his knowing that he was doing more than making the ordinary examination with the catheter in the bladder.

Dr. William M. Polk, of New York, thought that the slow progress made in the treatment of diseases of the ureters and pelvis of the kidneys was due to the difficulty in getting at the parts. Now the recognition of a distended ureter is comparatively easy. The reason for palpating between the bladder and the vaginal wall is perfectly clear. We can detect the distended ureters through the rectum also. The speaker then recounted his own experiments in this direction. He said we could unquestionably catch the ureter between its visceral extremity and the line of the uterine artery by a properly-shaped instrument, one blade of which would pass into the bladder and the other into the rectum. It is only necessary that the instrument be properly curved. He then discussed compression of the ureters.

Dr. Kelley, in replying, said that what he wished to impress upon his hearers was, that in palpation we have a very practical method of diagnosing diseases of the ureters and kidneys, and in catheterization, of diagnosis and treatment of diseases of these organs.

Dr. T. A. Emmett, of New York, read a paper on

URETHROCELE.

He excluded as a cause the want of support, which was believed in by so many. Urethrocele is often found to exist where there is a large double laceration of the cervix, and often where the woman has borne a number of children. An analysis of a number of his cases of urethrocele would show that it depends on: 1. Rapid delivery, with few but strong uterine contractions. 2. Delayed labor, where ergot has been used, or the forceps. He referred to the anatomy of the parts, and asked them to remember that the female had practically no internal sphincter. It is generally very necessary to thoroughly empty the bladder previous to delivery, yet the presence of a few ounces of urine may act as a cushion, and prevent the pressure from causing injury, while, if the pressure is too severe, the urine will escape. Nature often repairs these injuries herself, and when she does not, the result is a urethrocele. We should not call it a urethrocele when there is a swollen condition of the urethra and no injury has been received. Since 1882, when the author presented his button-hole operation to the profession, his experience has continued to convince him more and more of the benefit to be derived from its use.

Dr. Priestley, of London, England, thought he had described similar if not identical cases in the journals, long before Dr. Emmett. In speaking of these cases he would not venture to enter upon Dr. Emmett's well-known dexterity in all operations upon women. He reported the case of an English lady whom he and Sir Spencer Wells had under their care for some time, and who had been under the care of a universality of doctors, one of whom described it as a sebaceous cyst of the ovary which had descended into the bladder.

Dr. Skeene, of New York, thought that dislocation of the urethra and distention of the middle third were entirely different affections, though they may be due to the same cause. He is inclined to think that the dislocation is the much more frequent of the two. He thinks this laceration must be much more rare than we are given to believe by the paper. He can hardly see where an opening made in the centre of the urethra can restore a dislocation. He thinks it very good for a dilatation of the centre of the canal. Dr. Bozeman, of New York, ten or fifteen years ago clearly defined in the journals the dilatation of the urethra, and recommended, though he did not practise, opening of the middle portion of the canal.

Dr. William T. Lusk, of New York, has had marvellous success in

THE BUTTON-HOLE OPERATION

in the cystic dilatation of the urethra. He would prefer to close up the opening, but can rarely find the woman who will submit to it, as they always fear a return of the trouble.

Dr. Howard A. Kelley, of Philadelphia, referred at length to a case which is reported in full in the *Edinburgh Medical Journal*, which was operated upon by Skene Keith.

Dr. Emmett wished to call the attention of the Society, as did Dr. Skeene, to the entire difference between the sebaceous cyst and dilatation.

Dr. Engleman, of St. Louis, asked if in any of these cases the trouble ever returned.

Dr. Emmett had never known the condition to return after a complete cure unless the injury was repeated.

Afternoon Session.

Dr. R. Stansbury Sutton, of Pittsburg, read a paper on

PELVIC ABSCESS.

He limited his very brief and practical remarks to consideration of abscess following pelvic cellulitis. It was a disease very common among women, and was not confined to puerperal troubles. He spoke of two forms, septic and aseptic. As in many cases we cannot trace the septic origin, we are compelled to call them idiopathic, and lay the blame on "taking cold." Warm poultices were used, he thought, as much from their ancient usage as from the good they did. He prefers a blister, or, if that is not permitted, ice-applications. He endeavored in his paper to give the results of his own experience rather than to collect and collate the literature on the subject.

Dr. William Goodell, of Philadelphia: I have never seen pelvic abscess resulting from gonorrhœa. I have repeatedly found it resulting from septic poisons, and this, I think, is largely the cause of the trouble. It will often be caused by cold during the catamenial period, taking a bath, or, as I have known it to occur, from a woman sitting on the cold door-step watching a procession pass by. The treatment should be to first operate with as little danger to the woman as possible. When I can feel the pus I introduce a blunt instrument, as a pair of scissors. Whenever I can find the little fistulous opening into the rectum, I insert a little probe into it and cut on to this from the vagina, and change the rectal into a vaginal fistula, and the abscess disappears very rapidly. So far I have not failed; but some fistulas are so high up that you cannot do this. In some cases the abscess is so small, and extends so high into the rectum, that you cannot do this. It is my practice, as soon as I can feel an abscess opening into the vagina, to open it. I use bichloride injections, unless when it can pass into the rectum, and thus poison the patient, when I use the permanganate of potassium. If there is an iliac abscess, I search and find it, and, if possible, make an opening into the vagina. The worst cases are where the perineum is full of fistulous tracts. In these cases I try to get two to connect, and force a bichloride solution into them.

Dr. Parrish, of Philadelphia, thought that the aspirator should never be used in pelvic abscess unless for diagnosis. It is never curative. He believed in washing out with corrosive sublimate. He would hesitate to use a solution 1 : 1,000. In many cases it is not safe to wait till a distinct tumor is formed, and open into the vagina.

Dr. T. Gaillard Thomas, of New York, according to his experience has found

THREE FORMS OF PELVIC ABSCESS:

1. Inflammation of the broad ligament. 2. Of the cellular tissue between the vagina and the posterior part of the uterus. 3. The cellular tissue between the bladder and the uterus. Another form is that which is treated as pyo-salpinx. He thinks that the hazardous operation of laparotomy could often be avoided by opening and draining through the vagina. He thinks that many hard tumors, if explored, will show the presence of pus. The man who waits for constitutional symptoms in pelvic abscess will wait a long time. There are but two passages by which pus ought to be let out—through the vagina and the abdominal wall. If the abscess points and clamors for an outlet through the rectum I do not think it should be allowed to do so. I have seen two cases in which the patient died from evacuation through the rectum. Gases and fæces passed in through the opening. The evacuation should certainly not be made in the bladder. I use Goodell's modification of the German dilators, and always insert the drainage-tube. If the abscess is anterior to the uterus I separate the anterior vaginal wall precisely as I do in uterine extirpation. Pelvic abscess is almost always immovable; neoplasms, movable. This is the great diagnostic difference. Yet some pelvic abscesses are very movable, especially those posteriorly situated. Hence many are diagnosed fibroid tumors and cured by electricity. I use bichloride, 1 : 1,000. If the symptoms do not disappear I use stronger, but with fear and trembling.

Dr. W. Gill Wylie, of New York, thinks that cellulitis has always played too great a rôle in the etiology of pelvic abscess. Many abscesses, four out of five, occurring within a year or two after delivery, are due to salpingitis or ovaritis, and our best proof is from those who have opened the abdomen. Great mistakes are made by not distinguishing between those due to septic poison and ovaritis or salpingitis. It is of no use to open the vagina and leave a rotten ovary there. My views are, if you have pelvic abscess, patient dangerous, temperature 101° F., and sweating, I would open the vagina at once, belly at once, and find out just what can be done by the vagina. I have done it often, and if closed soon the danger is small. One patient died in New York, one in Chicago, from using an aspirator in pelvic abscess.

Dr. William Polk, of New York, believed pelvic abscess to be the direct result of tubal disease coming from the uterus along the lymphatics.

ASSOCIATION OF GENITO-URINARY SURGEONS.

Tuesday, September 18, 1888—First Day.

Dr. Edward L. Keyes, of New York, the President, addressed a few remarks of welcome and congratulation upon the past and prospective success of the Association.

Dr. Roswell Park, of Buffalo, read a paper on

PYÆMIA AS A DIRECT SEQUEL OF GONORRHŒA.

The case which the author used as the basis of his paper was one of ordinary gonorrhœa in the male, which had existed for several weeks, when the left knee became swollen and inflamed to a marked degree, and the right knee to a less, and soon after the patient lapsed into the so-called typhoid condition, with delirium, and finally died. Aspiration of the knee-joint had shown that it contained pus. The post-morten examination discovered pus in both knee-joints and an abscess at the left sterno-clavicular articulation. The mesenteric glands and bladder were normal. The prostate and the pelvic veins were not examined. There was sufficient evidence to show it to be a case of pyæmia as distinguished from septicæmia. Bacteria were found of the kinds ordinarily accompanying suppuration. The author thought that the pyæmic infection was the result of their entrance to the circulation through the diseased urethra. No gonococci were demonstrated in the pus contained in the abscesses. Genuine pyæmia is rare in connection with gonorrhœa, and should be distinguished from septicæmia.

The President remarked that he had never seen a case of pyæmic gonorrhœa, and in response to his inquiry, this proved to be the experience of the other members present. The author was not sure whether the patient had had a previous gonorrhœa. The President said that in a previously diseased urethra it was well known that non-infectious causes might excite suppurative urethritis, and he did not see why from such a condition pyæmic infection might not take place.

Drs. John P. Bryson and Edwin C. Burnett, then presented a communication entitled,

CLINICAL OBSERVATIONS ON GONORRHŒA, WITH SPECIAL REFERENCE TO ETIOLOGY, DURATION, AND TREATMENT.

The paper was based upon observations upon one thousand three hundred and ninety-four cases of gonorrhœa. The conclusions from these observations were: (1) That gonorrhœa is a specific disease; (2) the gonococcus of Neisser is an essential etiological factor; (3) the abortive treatment is inefficient and harmful; (4) local treatment of all kinds is not justified in the first and second stages; (5) we recognize in the disease a marked tendency to persist in the chronic stage; (6) the tendency to become chronic and to persist appears to be increased by the use of topical treatment in the first and second stages; (7) the so-called methodical treatment, that is the internal administration of remedies, combined with the proper hygienic and dietary regulations, does most to shorten the duration of the disease; (8) all local applications should be reserved for the third, or declining and chronic stages. The author thought that the failure of bichloride of mercury and other germicide injections to abort the disease, was due in large part to the impossibility of reaching and destroying all the infectious germs which are known to invade deeply the mucous membrane.

Dr. Taylor, of New York, expressed disbelief in the gonococcus of Heisser or of Bumm as the cause of gonorrhœa.

Dr. Sturgis, of New York, entertained the same disbelief.

The President remarked that the "positive evidence," which he possessed on the subject, might be described as negative, and the negative evidence as positive; to wit, no gonococcus no transmission to another of the disease; while, on the contrary, gonococci might be plentifully present in the discharge and not convey the disease to another person with whom there had been contact.

Dr Edward R. Palmer, of Louisville, Ky., read a paper on

RETROJECTIONS IN GONORRHŒA.

Bichloride and hot-water irrigation with a Keifer nozzle twice or three times a day, is the plan preferred by the author. The bichloride should not be stronger than one to ten thousand at the most and usually much weaker—about one to thirty thousand is most likely to prove best; strong injections, as one to five thousand, are likely to do much harm. The value of this treatment is not so great as its advocates have claimed, and it is best when it is used in connection with the ordinary astringent injections —"mixed" treatment, as the author described it, and such astringent injections will usually be found necessary to complete a cure.

Dr. Sturgis had obtained only negative results with the hot water and bichloride retrojections. The "mixed" treatment, he thought, detracted from the value of the results attributable to retro-injection.

Dr. Bangs got favorable results after he had learned skill in using the irrigation. Cold water is as good or better than hot.

Dr. Taylor showed a Keifer nozzle as modified by Bangs, possessing advantages over the original, in his opinion.

The President was in favor of irrigation, and prescribed three or four daily to be used by the patient by aid of his "universal injector."

Dr. F. R. Sturgis, of New York, read a paper on

LOCAL TREATMENT OF CHRONIC URETHRAL DISCHARGES.

He referred to the difficulties encountered by the surgeon in this field. He regarded as chronic a discharge which had existed for more than four or five weeks. Treatment should be directed to relieving the congested and inflammatory conditions. This is one stage. After this comes exudations in the submucous tissue and thickening, not general but at certain points. These inflamed parts keep up the discharge. In addition to this granulations may be formed. The glands alone may be affected. He then spoke of the method of treatment which for several years he had employed. This consists in the application through the short endoscopic tube of solutions of nitrate of silver by means of a cotton-holder to the diseased area. The advantage claimed for this method is that the application can be definitely limited, and that thus a much stronger solution may be used than can be employed with the ordinary method by injection; from twenty to sixty grains to the ounce, or even a saturated solution, thus used causing very little pain or subsequent irritation.

Dr. John A. Fordyce, of Chicago, by invitation, read a paper entitled

THE VIEWS OF DR. OBERLÄNDER, OF DRESDEN, ON THE DIAGNOSIS AND TREATMENT OF CHRONIC URETHRITIS,

with demonstrations of instruments.

Dr. Oberländer advocates the endoscope as an aid in the diagnosis of chronic gonorrhœa, and prefers the Nitze instrument as modified by himself, to that of the new Leiter instrument, as well as all others in which reflected light is used. As the result of his endoscopic observation he has founded a new pathology of urethritis. He describes affections of the mucous membrane, without participation of the glands of Litter; and inflammation of these, with and without obstruction of their ducts. All cases of chronic urethritis are treated by him by means of a modified Otis dilator, covered with a thin india-rubber sheath. The dilatation is carried to from 30 to 40 Charrier. After the dilatation a solution of nitrate of silver (1 to 2,000) is injected through a soft rubber or Ulltzman catheter. He claims in this manner to reach the deep-seated glandular inflammation.

The Secretary read a paper by E. Henry Fenwick, F.R.C.S., of London, England: "The Prognosis of Stricture Based on Thirty Years' Death-record at the London Hospital, and the Practice at St. Peter's Hospital."

Dr. Samuel W. Gross, of Philadelphia, read a paper entitled

CONNECTION BETWEEN MASTURBATION AND STRICTURE.

In over three hundred cases, eighty-eight per cent. of masturbators observed by the author, in which there had not been attacks of gonorrhœa or other cause to account for the condition, organic strictures were found. Of these strictures, eighty-two per cent. were within one-third of an inch of the urethral orifice, the remaining eighteen per cent. were deeper, and situated at various points; some single, others multiple.

Dr. R. F. Weir, of New York, remarked that he had found similar constrictions in young infants. He thought too much stress was placed upon these constrictions in masturbators as pathological products.

Dr. R. W. Taylor, of New York, said that in these cases he had found tumefied bands or constrictions by endoscopic observations.

The President called attention to the existence of normal constrictions in the urethra demonstrated by Weir by means of casts of the urethra, and, more recently, by Antal by the use of his ævo-urethroscope.

In reply Dr. Gross thought there could be no doubt as to the existence of those strictures which he had described at or near the meatus, whatever was said of the deeper ones. In his cases often there was severe pain on passing the bulbous explorer, and bleeding in some, and in some other cases the patient was anæsthetized, so that spasm was eliminated in these cases at least.

Dr. Edward L. Keyes, of New York, read a paper on

THE CURABILITY OF URETHRAL STRICTURE BY ELECTRICITY; AN INVESTIGATION.

The object in making this study is an endeavor to clear up the mists which have hitherto surrounded it, and by unprejudiced personal clinical study to find what results could be obtained. Dr. Keyes' previous acquaintance with electricity in the urethra was a trial of the old method, that of Mallet and Fripier. The result upon ten cases treated in December, 1871, at Charity Hospital was total failure in all. The new method of electrolysis—mild currents at long intervals, the method known most familiarly as that of Dr. Newman—has been tested in the present communication; seven cases from dispensaries form the material from which conclusions were reached. Three were treated by Dr. Keyes, three by his assistant, Dr. E. Fuller, one by Dr. Robert Newman, who kindly consented to accept the case in order that he might demonstrate the efficacy of the treatment by the result; all were total failures. The case treated by Dr. Newman apparently the *most* conspicuous failure. One other case of spasm without organic stricture is mentioned in the paper as having been (possibly) benefited. Another case of the disastrous results of the use of strong currents was exhibited in the person of a patient treated by another physician. His study, Dr. Keyes concluded, of the subject, and the experience it had brought him, digested with all the impartiality he possessed, led him to state that the claim that electricity, however employed, is able to remove organic urethral stricture, lacks the requirement of demonstration.

Several members related their experience with electricity in treating stricture, all of which tended to corroborate the conclusions of Dr. Keyes.

AMERICAN NEUROLOGICAL ASSOCIATION.

Tuesday, September 18th—First Day.

Dr. James J. Putnam delivered the

PRESIDENT'S ADDRESS.

in which he recommended to the Society the adoption of some system of collective investigation by which the daily hospital and dispensary work of members might be better utilized. He referred to the excellent work begun by the British Medical Association in 1881, to the report on collected cases by Sir William Gull at the Copenhagen Congress in 1884, to the facts investigated by the Berlin Medicinische Verein, and to the good work once done for a short time by the New York Therapeutical Society. There were such subjects as the uses of iodide of potash, brain-tumors, functional neuroses, and cranial measurements, in the study of which collective investigation would prove of great value. Another subject of interest would be the effect of small quantities of lead in predisposing to disease. He has found minute quantities of lead in the urine of healthy as well as sick people. In the urine of three out of twenty-three healthy medical students he discovered lead. It might not be detrimental to health, and yet might predispose to neuroses. He recommended a collection of microscopic specimens—brains, crania, etc., or photographs of such—which, kept by the secretary, would prove useful to members who might desire to consult them.

Dr. Philip C. Knapp, of Boston, then read a paper entitled

NERVOUS AFFECTIONS FOLLOWING INJURY (CONCUSSION OF THE SPINE, RAILWAY SPINE, AND RAILWAY BRAIN).

He reported eleven cases, and drew the following, among other inferences: Concussion of the spine, although probable, is a matter of doubt. Muscular strain, spinal irritation, and peripheral neuritis are not uncommon complications. Injuries may give rise to gross mechanical lesions, but also to chronic insidious, degenerative processes, to functional affections, psychoses, and states of hysteria and neurasthenia. Both hysterical and neurasthenic states may be superimposed upon organic disease, thus obscuring diagnosis.

Dr. E. C. Seguin was disposed to agree with the conclusions of the author. The possible deception of patients must be borne in mind. In some cases hysterical or neurasthenic states antedate injury. Subjective symptoms are of doubtful value, because they may be simulated or the result of auto-suggestion. Simulation of the most complex nervous diseases may be produced by the new hypnotism, either through suggestion of an operator or by auto-suggestion, as has been pointed out by Bernheim. He referred to publications of his in 1875 concerning the coexistence of hysteria with organic diseases of the brain and cord. There is no doubt of the reality of neurasthenic conditions following severe physical injuries or moral shocks.

Dr. L. C. Gray said that it would, in medico-legal cases, be necessary to demonstrate clearly to a jury the facts which are learned. It is sometimes hard to discriminate between malingering and actual suffering. People injured are followed up by runners for lawyers, and by them impressed with the dangerous nature of their injuries. Then the slow processes of law force them to remain in a condition of ill-health. They cannot afford to get well for fear of a suit for conspiracy. This develops in the patients a psychical condition worse than hysteria.

Dr. Zenner bore witness to the fact that hysterical symptoms occurred in a great many cases of organic disease. But functional troubles are really due in great part to impairment of the nervous system. He saw a case of tremor lately, following mild lead-poisoning, where two or three applications of hypnotism removed the tremor. Deception by a patient should not lead one to believe that there is no injury present. Pure malingering is very rare.

Dr. Putnam agreed with Dr. Zenner as to malingering. The simulation of hemianæsthesia is so difficult that when present it is a valuable aid to diagnosis.

Dr. Knapp closed by saying that the tendency to auto-suggestion would naturally be greater in medico-legal than in other cases.

Dr. Isaac Ott, of Easton, Pa., read a paper upon

HEAT-CENTRES IN MAN,

demonstrating the fact that in man there are heat-centres in the corpus striatum. He adduced the evidence of disease in support of this statement. Pathological phenomena also make it probable that heat-centres exist in and about the fissure of Rolando.

Dr. Putnam thought it would be well if Dr. Ott would formulate questions for neurologists to answer in looking into their cases. The localization of the heat-centres might be greatly aided in this way.

Dr. Hare was not disposed to agree with the author of the paper. He said that in researches the cells were destroyed, and then it was claimed that a heat-centre was discovered, when in reality it was an inhibitory heat-centre.

Dr. L. C. Gray asked if Dr. Ott had measured the heat through the skull. He thought that the heat-centre might be located in this manner. Cerebral thermometry might be used in this connection. He had shown, ten years ago, a great variation of the temperature of the head even in normal conditions.

Dr. James H. Lloyd referred to a case of his own, with subnormal temperature and a parietal cortical lesion.

Dr. Ott said that the taking of temperature in nervous cases more frequently might be of great assistance in the localization of the heat-centres.

Dr. E. D. Fisher, of New York, then contributed a paper entitled

A CLINICAL REPORT OF CASES OF EPILEPSY FOLLOWING CEREBRAL HEMIPLEGIA.

The author referred to some twenty-eight cases. The etiology was meningeal hemorrhage, thrombosis, embolus, parencephalus, poliencephalitis, and cerebral hemorrhage. Sometimes epilepsy did not follow for some months, or even years, in these cases, and was rather more often of the idiopathic variety than the Jacksonian type. He drew the conclusion that, as these cases were of known cortical origin, and as they resembled clinically the ordinary attacks of idiopathic epilepsy, the seat of origin of both is the same—that it is in the cerebral cortex.

The paper was discussed by Drs. Knapp and Walton.

Dr. Robert T. Edes, of Washington, read a paper on

THE RELATION OF RENAL DISEASES TO DISEASES OF THE NERVOUS SYSTEM.

The author discussed the effects of renal diseases, such as chronic diffuse nephritis, in producing numerous nervous symptoms, such as muscular twitchings, changes in the pupils, headaches, insomnia, stupor, convulsions, etc. He thought we should not call all these the result of uræmia. The retention of urea in large quantities had been proved not to be so dangerous as formerly believed. He would classify the causes of these symptoms of renal disease under the headings neurotic, angio-neurotic, angio-notheutic, angiohydræmic, urotoxic, and uroseptic. There can be uræmia in conjunction with a considerable flow of urine. Epilepsy may coexist with nephritis and give rise to error in diagnosis. True insanity may occur before actual renal disease is discovered, but in his opinion it is not uræmic. Uræmic hemiplegias might be better explained as due to a unilateral œdema than to the poisons affecting one side of the brain.

Dr. F. X. Dercum agreed with the author in a general way, yet thought deductions should be carefully drawn in the present state of our knowledge. We must still regard urea as a dangerous thing. He spoke of the occasional difficulty of diagnosis between apoplectiform attacks and uræmic convulsions. In uræmia there is, as a rule, depression of the temperature. He should try the morphine treatment of Bright's disease mentioned by Dr. Edes.

Dr. Seguin said that patients often present themselves for treatment for headaches, occipital in character or often like real migraine, that these and other paræsthesias of the head were often attributable to uræmia in a prealbuminuric stage of Bright's disease. In such cases there is, as a rule, increased arterial tension and active heart. Casts are often discernible in the urine, but albumin rarely. There are generally symptoms of indigestion. He had often found in post mortems upon cases of dementia paralytica contracted kidneys, and thinks that to this may be due some of those epileptiform and apoplectiform attacks so frequent in this disease.

Dr. L. C. Gray related several cases illustrating the difficulty of making a differential diagnosis at times between certain cerebral diseases and nephritic sequelæ similar in character. He detailed one case of mania coexisting with pyuria.

There was further discussion by Drs. Dercum and Zenner, and the discussion was closed by a few remarks from Dr. Edes.

Dr. C. L. Dana, of New York, contributed a paper on the

CORTICAL LOCALIZATION OF CUTANEOUS SENSATIONS.

The author, from a review of one hundred and thirty-seven cases of cortical lesion, finds a complete identity of the motor and sensory cortical areas. A deeper lesion is apparently more common where there is anæsthesia.

Dr. C. K. Mills thought that though the facts and arguments were strong, Dr. Dana's inferences were not altogether justly drawn. He had recently occasion to go over the same ground. The writer's own four cases did not demonstrate the matter fully. There are certainly large numbers of lesions in the motor cortical area, but without anæsthesia.

Dr. M. Allen Starr believed the localization of cortical centres of sensation to be still an open question. He referred to recent embryological investigations as regards the motor and sensory tracts in the fetal brain, which rather favored Dr. Dana's conclusions. Zuckerkandl's work in comparative anatomy, following in the path of Meynert, is also very valuable. In the selection of pathological cases it is necessary to exercise great care. Many of those he had collected are unsatisfactory. He differed from Dr. Mills, who had stated that lesions of the hippocampus have not been looked for. The hippocampus lies immediately upon the crus cerebri, and a lesion affecting one and not the other was hard to find. This fact vitiates many of Ferrier's experiments and conclusions. He believed the tactile areas of each side of the body were represented on both sides of the brain, as is the visual surface of each eye. Thus, in many cases of hemiplegia the normal hemisphere may compensate for the lesion in the other.

Dr. Seguin strongly favored the cortical localization of sensation. He had seen Schiff remove parts of the cortex in dogs, and the positions assumed by the limbs were only explicable on the supposition of anæsthesia. He had frequently studied the sensory auræ in Jacksonian epilepsy from brain-tumors and other local lesions. Peculiar paræsthesias often precede the spasms. He described the case of subcortical tumors operated upon by himself and Dr. Weir, which is a case that would support the conclusions of Dr. Dana.

After the closing of the discussion by Dr. Dana, the Society went into executive session and the following new members were elected:

Drs. H. R. Stedman, Morton Prince, W. N. Bullard, of Boston; Drs. William Noyes, S. B. Lyon, Frederick Peterson, of New York; Dr. C. H. Hughes, of St. Louis; Drs. E. N. Brush, and William Osler, of Philadelphia; Dr. S. Ayres, of Pittsburgh; Dr. L. W. Baker, of Baldwinsville, Mass.

AMERICAN OTOLOGICAL SOCIETY.

Special Meeting, Tuesday, September 18, 1888.

Dr. J. S. Prout, of Brooklyn, President, in the Chair.

Dr. S. O. Richey, of Washington, read a paper on

THE PRIMARY PHYSIOLOGICAL PURPOSE OF THE MEMBRANA TYMPANI.

He reviewed the anatomical development of the different parts of the ear from the lower to the higher forms of animal life, as change of environment demands some additional structure to aid in the preservation of individual existence. Attention was asked to a parallel in the evolution of the eye, the lungs, and the ear; and it was argued that the primary purpose of the drum-membrane is protection; that transmission of sound-waves is a secondary purpose, and made necessary by the existence of the protective membrane. The membrana tympani exists for the protection of the tissues of the middle ear from the desiccating influence of the atmosphere, and the rigidity that would therefrom ensue. The higher the development of a species, the smaller will the labyrinth be found, and the less fluid it will contain.

With the exposure to the air, consequent upon loss of the membrana tympani, this fluid is diminished by exosmosis through the membrana secondaria and its subsequent evaporation; thus lessening the effect of sound-waves upon the perceptive filaments. In "progressive deafness," or aural atrophy, this same influence is exerted through the Eustachian tube, which is ordinarily of greatly enlarged calibre, and dry with the dry nose and pharynx. The writer's conclusions were:

First. The primary purpose of the tympanic membrane is that of protection to the tympanic cavity from the evaporating influence of the air, to prevent parching and stiffening of the membrana secondaria, the joints of the ossicles, and the tendons of the tympanic muscles.

Second. It being necessary for the protection of the cavity, is modified into part of a transmitting mechanism by the existence of the ossicles and their attachments—a secondary physiological purpose.

Third. A permanent opening of the membrane may, under given circumstances, temporarily improve the function of hearing, but is harmful to the ultimate condition of the organ.

Fourth. The tendency of the membrane to heal is an effort on the part of nature to preserve the function of hearing from the effects of disease, or ill-advised surgical interference.

Dr. Gorham Bacon, of New York, reported a case of

CEREBRAL ABSCESS, FOLLOWING EXTENSIVE NECROSIS OF THE TEMPORAL BONE. OPERATION. DEATH FROM SECONDARY HEMORRHAGE. AUTOPSY.

A man aged thirty had chronic purulent discharge of two years' standing when first seen, September, 1887. Polypi and granulations were removed from the left ear, but there was difficulty in keeping the passage properly open for drainage. There had been extensive necrosis, and a large sinus led upward from the meatus. There was some pain in December, and in January left facial paralysis occurred; and at the end of that month an abscess was opened above and behind the auricle, which was found to communicate with the sinus before mentioned. A drainage-tube was introduced into the opening and brought out through the sinus, and the cavity was washed out regularly with a bichloride solution. He improved and got to walking out. March 7th, he complained of great pain in the forehead and neck, his temperature rose to over 102°, he grew very restless and became aphasic, being only able to answer "Yes, sir!" to everything said to him. Next day he was much the same. No recent paralysis, fundus of both eyes normal, boggy swelling over the left malar prominence and eyelids. There had been no evidence of mastoid involvement, and an incision over this region yielded negative results.

Dr. Robert F. Weir, of New York, saw the case at this time, divided the temporal muscle, cleared out the suppurating tract, and thrusting the finger deeply toward the base of the skull, found a pulsating swelling, which was explored, then opened, yielding a half-ounce of pus. The patient improved, but forty-eight hours later became more stupid again. Then a counter-opening was made over Broca's convolution. No pus was found, but a drainage-tube was carried through the brain-substance and out of the other opening. Again he improved, but forty-eight hours later died of secondary hemorrhage, supposed to be due to injury of the middle cerebral artery in the process of introducing the drainage-tube.

Dr. O. D. Pomeroy, of New York, reported a case of

CHRONIC SUPPURATIVE OTITIS WITH METASTATIC IRIDO-CHOROIDITIS, AND ABSCESS OF THE SIDE OF THE NECK COMMUNICATING WITH THE TYMPANUM.

This occurred in a man of about fifty, first seen in consultation, on account of iritis with firm adhesions. He had the otitis some months before and had been apparently cured, but had for some time been suffering from great soreness in the neck, ascribed to muscular rheumatism. A week later there was pus in the anterior chamber. Paracentesis was done and the incision kept open, but perforation occurred in the upper part of the sclera, and the abscess pointed in the upper lid. Subsequently the eyeball was enucleated, when firm adhesions were found between it and the ocular conjunctiva. A week later there was decided increase in the swelling in the side of the neck, and deep fluctuation could be detected. Previous to this exploratory puncture had given no pus; but now a deep incision evacuated about four ounces. and pressure on the abscess caused it to well up also from the external auditory meatus. This occurred in July of the present year; subsequent improvement was rapid, and the patient is now well.

Dr. C. H. Burnett, of Philadelphia, read a paper entitled

CHRONIC PURULENT INFLAMMATION OF THE TYMPANIC ATTIC,

based on notes of ten cases of the disease, additional to ten cases already published elsewhere. The chief obstacle to cure in these cases is the limited drainage through the membrana flaccida above the short process of the malleus, where the perforation in such cases is usually situated.

The drainage is further reduced by the fact that the disease is in and about the head and body of the malleus and incus, and these act as a dam to the free outflow of matter. This in turn decomposes, keeps up the disease, and renders the patient liable to intra-cranial abscess, or general pyæmia. In treatment, therefore, the chief considerations are cleansing and draining the upper cavity of the tympanum. This is best done by injections, by means of the tympanic syringe, of peroxide of hydrogen, or three per cent. to five per cent. carbolic-acid solution; and by enlarging the perforation and exposing the attic, either by scratching off some of the margo tympanicus, or by excision of the membrana tympani, and removal of the ossicles, *i.e.*, the malleus and incus.

Dr. Samuel Sexton, of New York, read a paper on

EXCISION OF THE DRUM-HEAD AND OSSICLES FOR THE CURE OF CHRONIC PURULENT INFLAMMATION OF THE ATTIC OF THE TYMPANUM.

In most cases of persistent otorrhœa the tympanic attic is the seat of disease, and it is difficult to reach it with remedies. While casting about for a better mode of treatment he had been struck with the recent advances in the surgery of the joints; and reflecting on the resemblance of these cases to those of chronic joint disease, in the chronic muco-periosteal inflammation, caries of the bony walls, and synovitis of the articular surfaces of the ossicles, had been led to try the removal of diseased structures, and the securing of efficient drainage. These cases constitute a large class, the hearing is greatly impaired, the ear irreparably damaged, the parts to be removed are useless and obstruct drainage. Even if temporarily relieved the trouble is liable to break out again, and life is continually endangered. Besides, this treatment will often greatly improve the hearing. Though we may not be able to apply antiseptics here as freely as to joints, we can secure the essential point, free drainage. The operation had been previously described. Even if the chorda tympani nerve was severed no permanent inconvenience resulted.

Dr. Samuel Theobald, of Baltimore, read a paper upon

THE EMPLOYMENT OF BORACIC ACID IN SOLUTION, IN THE TREATMENT OF OTITIS MEDIA SUPPURATIVA.

In the ordinary cases of chronic suppurative otitis media, in which there is usually extensive destruction of the drum-head, he uses boracic acid in powder, applying it by means of insufflation; but in acute cases and in chronic cases in which the destruction of the drum-head is not extensive, and in which a closure of the perforation may be anticipated, he prefers to use a saturated solution of boracic acid. The advantages claimed for the solution in such cases are, that the healing of the perforation in the drum-head is more certain to be brought about when it is used than when the powder is employed, since the latter, by too suddenly drying the ear, and also by the mechanical action, frequently prevents the restoration of the membrane; that in acute cases it is safer, as it cannot obstruct the free escape of discharge from the middle ear as the powder sometimes does; and that it can be applied more effectually than the powder can by unskilled hands. In his own case no serious consequences had ever resulted from the application of boracic-acid powder to the ear; but reference was made to the three reported fatal cases of suppurative inflammation of the middle ear, in which the fatal result was attributed to the introduction of boracic acid, in two by packing, in the other by insufflation. The solution (fifteen grains to the ounce) should be used to syringe out the ear, three times a day if the discharge is profuse, less frequently as the otorrhœa declines.

In office practice it is more convenient, after having cleansed the ear, to instil the solution with a pipette. Cases were related illustrating the good effects of the treatment, especially in acute suppurative otitis media.

Dr. J. Oscroft Tansley, of New York, read a paper on

NASAL DIFFICULTIES IN EAR DISEASE.

The important conditions are: Whole or partial occlusion of one or both nostrils by hypertrophies, preventing the removal of secretions and causing venous congestion by attempts at such removal; deviated septum, œdematous tissue, and hypertrophied tissue in special situations acting in much the same way. Hypertrophied tissue pressing on the Eustachian tube, bands of tissue in the pharynx, apparently cicatricial, atrophic rhinitis with a patulous condition of the tubes, and secretive catarrhs are also important causes. He does not employ the galvano-cautery, for fear of exciting purulent inflammation in ears usually strongly predisposed to such an outbreak. The indications for treatment are: 1. To combat the blood dyscrasia or catarrhal diathesis. 2. To cure the inflamed mucous membrane and restore its normal function. 3. To free the nasal and nasopharyngeal cavities of all obstruction, and encourage nasal breathing, relying mainly on the snare, sprays, and mild astringents.

Dr. W. H. Carmalt exhibited

IMPROVED CANNULAR AURAL FORCEPS AND SCISSORS,

the improvements consisting in a handle that would avoid undesirable motion, a biting forceps, and a pair of cannular scissors.

Dr. Clarence J. Blake, of Boston, had prepared a paper, read by Dr. John Greene, on

THE INFLUENCE OF THE USE OF THE TELEPHONE ON HEARING POWER.

He believed this would be bad, because the very low intensity of the sounds, as demonstrated by experiments, necessitated a very fatiguing effort on the part of the ear, which placed it in a condition in which it was especially liable to injury from the shocks of the metallic sounds of high intensity liable to be heard at any time through making or breaking the circuit.

After a brief executive session the Society adjourned.

AMERICAN DERMATOLOGICAL SOCIETY.

TUESDAY, SEPTEMBER 18TH—FIRST DAY.

Dr. I. E. Atkinson, of Baltimore, delivered the

PRESIDENT'S ADDRESS,

in the course of which many of the more recent advances in dermatology were discussed, and especially the influence which bacteriology has exerted upon certain processes. In pathogenesis, he believed, resides the essence with which the science of medicine must become familiar before it may hope to attain a definite and established position. Pathological anatomy only reveals the effects of influences more or less determinate.

THE SOUL OF PATHOLOGY IS ETIOLOGY,

and we have learned that a correct understanding of disease depends no more upon pathological processes and results than upon pathological causes. A morbific agent may produce widely different results, varying with the locality of its activity. The skin, no less than other organs, presents, in its pathogenesis and pathology, analogies and homologies; as the circumscribed baldness of alopecia of tropho-neurotic origin, and that occasionally observed in the course of syphilis, of the urticaria following dietetic errors, and that observed in malaria, of facial herpes in acute lobar pneumonia and in remittent fever. Eczema may result from local cutaneous irritation, and also from unknown systemic influences. In rubella or German measles, and rubeola or measles proper, we have two morbific principles which we have abundant reasons to believe unrelated, but which produce results that are often almost identical. Suppuration justly claims a high interest for us. Pus, it appears, is only formed in the presence of certain minute organisms, but more recent research makes it probable that not the organisms themselves but their products—ptomaïnes—are the agents which bring about suppuration in the tissues. In the absence of ptomaines, it would appear that pyogenic micro-organisms are incapable of exciting suppuration. In cutaneous suppurative processes most interesting considerations are presented, and we are prepared and partially justified in receiving with credence some recent bacteriological observations attesting the influence of these organisms. Impetigo, furunculosis, and sycosis have been found to be produced by the invasion of staphylococcus pyogenes aureus et albus. The differences in these diseases depending upon the depth to which the bacterium penetrates, and to the varying anatomical structure. The rôle of pyogenic bacteria is no less important in the secondary processes of affections primarily specific. Guttmann attributes the pus formation, but not the contagion, to organisms found in smallpox. The suppurative process thus illustrates that not only may apparently dissimilar morbid actions have a common origin, but that identical results may follow the action of dissimilar causes. Many affections are considered as skin diseases, and are designated as such only because we are unacquainted with the subtle and remote pathological processes of which they are expressions. It is likely that various forms of dermatitis exfoliativa, of pemphigus, of dermatitis herpetiformis, among others, are such. Kaposi vehemently objects to Duhring's dermatitis herpetiformis including in its severest forms the impetigo herpetiformis of Hebra, an affection occurring in puerperal women and terminating fatally in the great majority of cases. He has, however, recently admitted that the affection may attack men as well as women. The varied character of the general symptoms and of the pathological alterations teaches us that the eruption can hardly have a constant and characteristic etiological relation to any defined morbid process. Post-mortem examination shows internal disorders, pyæmic processes, tubercular lesions, cerebro-spinal affections. The lesions have, however, not been constant. If we accept Hebra's opinion that impetigo herpetiformis depends on a reflex nervous and vascular irritation, we may conclude that this irritation may originate in pyæmia, or tuberculosis, or other agency acting upon the trophic centres; and if the impetigo be secondary, it should not be considered as a special disease. Duhring has made it evident that under the designation of dermatitis herpetiformis it becomes possible to group together affections heretofore considered distinct, and that we should admit it to our text-books just as purpura is admitted. Lesions of the cerebro-spinal system have been found after death, seemingly attesting the secondary character of the cutaneous lesion.

Many cutaneous affections are thus seen to have a varying etiology, and the dependence of skin-lesions upon disease of the central nervous system and of the viscera is abundantly evident; but until pathology discovers whether the influences are constant and what is their exact nature, we cannot expect that diseases will be considered so much as what they are as what they appear to be.

Dr. G. H. Rohé, of Baltimore, Md., read a paper on

THE ELECTROLYTIC DECOMPOSITION OF ORGANIC TISSUE.

Many compounds in a fused or liquid state, he said, may be decomposed by passing through them a current of electricity of sufficient strength to overcome the chemical affinity between the component molecules. This is called electrolysis, and a number of laws governing it have been established by the labors of Faraday and others. Thus electrolysis does not take place in solids; bodies must be in a state of fusion or solution. Decomposition occurs only at the surface of the electrodes immersed in the electrolyte. Whenever an electrolyte is decomposed by a current of electricity, the resolved ions have a tendency to reunite, thus setting up an opposing electro-motive force to the decomposing current. This tendency to reunite is commonly termed "chemical affinity." When water is decomposed by a current of electricity into its constituent ions, oxygen and hydrogen, the opposing electro-motive force due to the chemical affinity of these two gases is about 1.5 volt. Therefore, to decompose water, a battery having a higher electro-motive force than 1.5 volt is necessary. Inattention to this fact may account for the contradictory results obtained in some cases where electrolysis is employed for therapeutical purposes. The quantity of the substance which is decomposed is proportional to the quantity of electricity passing through the electrolyte, and is independent of the size of the electrodes and of the time the current passes. The amount of electro-chemical action is equal at all points of the circuit. This law seems to contradict the law that decomposition takes place only at the surface, so that both propositions must be accepted with reservations.

The theory of Clausius is that "every molecule of a fluid moves about in an exceedingly irregular manner, driven by other molecules themselves in a state of agitation. This molecular agitation goes on at all times, independently of the action of electro-motive force." In every compound a certain proportion of the molecules at any instant are broken up into their constituent atoms. The electro-motive force does not produce the disruptions and reunions of the molecules, but, finding them already going on, it influences the motion of the constituents during their intervals of freedom. The amount of this influence is proportionate to the electro-motive force when the temperature is given. The conductivity of electrolytes increases as the temperature rises. Pure water is said not to be an electrolyte, inasmuch as it is a non-conductor, yet most of the laws of electrolytic decomposition have been deduced from observation upon slightly acidulated water, and it seems probable that salt or acid added to the water promotes electrolysis by increasing the conductivity. Galvanic conduction through liquids is probably always electrolytic, and, if this be true, many of the current notions of the physiological action of the galvanic current upon organic tissues require modification. We must assume that every time we use the constant galvanic to relieve pain, to stimulate nutrition, or to perform electrolytic operations, we are performing electrolysis, for the human body may be regarded as a large and exceedingly composite electrolyte. The process termed electrical absorption, electrical osmosis, or electro-catalysis, will properly be ranged under the term electrolysis. Organic tissue is an electrolytic conductor, and a current can pass through it only by electrolytic decomposition of its compounds. Hitherto the human body has been measured electrically simply as a conductor or as a resistance, but it seems to the author much more rational to regard it as an electrolyte. In electrolysis it seems probable that the watery portions of organic tissues, together with certain salts and acids in solution, yield to the disruptive power of the current, and hydrogen, with other electro-positive ions, is set free at the negative electrode, while oxygen and negative ions are separated at the anode.

In the author's opinion there is a "shaking up" of the interpolar compounds. If the current is of moderate strength, improved nutrition will result if the tissues have normal vital resistance. If the current be excessive, nutrition will be unfavorably affected. If the tissues are normal, recovery and repair of slight defects may promptly take place, but in inflammatory infiltrations, new-growths, etc., a molecular disturbance of some extent or continued for some time, the author believes, may produce retrogressive metamorphosis. He is also of opinion that in many pathological products a retrogressive change begun under an electrolytic current is kept up after the current is discontinued.

One case of goitre treated by electrolysis is reported in which the tumor not only grew smaller during the treatment but continued to do so after its cessation, until it has now practically disappeared. The author's experience with electrolysis in fibromata, vascular nævi, and epithelial and papillary neoplasms strongly corroborates that of others. He is led to ascribe this continued effect to a modification of vital activity impressed upon the tissues by the electrolytic current.

The author goes on to describe the strength of current necessary to employ in the destruction of hairs upon the face and new-growths, and drops a good word in passing for electrolysis in the treatment of stricture of the urethra, believing that this method of treatment will become a well-recognized one so soon as we know better how to use it.

Dr. Heitzmann spoke of the favorable results reported in the treatment of keloid. Althaus, of London, first advocated the method for this affection twenty-five years ago, but some years ago, when this distinguished surgeon was in New York, he stated that he had given up electrolysis in treating keloid. Dr. Heitzmann had used it in one case of keloid without very favorable results.

Dr. Morison said that hypertrophic scars, in his experience, were rendered flat and white, the superficial veins were cut off, and the results of electrolysis were altogether good. He had treated keloid in a negro with good results, and could state that he was a firm believer in electrolysis.

Dr. Fox had employed the method in four or five true keloids, and although the results were at first promising, the only permanent good effect was the cutting off of superficial veins, and at the present time he could say nothing very favorable of it.

Dr. Hyde confirmed the views of Dr. Fox. In one case, which seemed favorable for electrolysis, he had been much disappointed, and left it about in the same condition as when treatment was begun.

Dr. Rohé said he had not treated a well-marked case of true keloid, but in hypertrophic scars he had had some results as good as those of Dr. Morrison.

Dr. Heitzmann, of New York, then read a paper upon

THE VALUE OF SALICYLIC ACID IN DERMATOLOGY.

During the past three years he had made extensive use of salicylic acid in the treatment of a great variety of skin-affections, and both on account of its great efficacy, its cheapness, and its freedom from the disagreeable features of such other remedies as tar, chrysarobin, and like preparations which smell disagreeably and stain the clothing, he has found for salicylic acid a wide range of usefulness. The peculiarities of the drug are that it acts upon the horny layers of the skin. With the exception of acetic acid no agent is so active in softening and finally destroying hypertrophied epithelial tissues, and as it is at the same time a valuable parasiticide, a very large field was opened for the drug in dermatological practice. None of us expect that any one remedy will benefit all kinds of skin disease, and in experimenting, "beliefs" and "impressions" must not be taken into account. We must have definite facts and scientific proofs.

The author's observations have extended to twenty-four different varieties of skin-lesion. The remedy can be applied in three ways: 1, As a powder; 2, as a plaster or salve; 3, as a solution. It was first advocated by Lassar and subsequently by Unna, but the author does not think its worth is yet fully appreciated, and its advantages over tarry preparations well enough known. The solution is best made in alcohol, as the drug is not very soluble in water, and from this solution any desirable watery solution can be readily made.

Hyperidrosis is greatly benefited by it. It is now used, as it has been for the past twelve years in the German army, as a deodorizing agent. The regulation application for the soldier's feet is a one per cent. mixture in tallow. The results are very favorable.

Seborrhœa of the face, when combined with acne, rapidly improves under its use, and, in fact, the results may be called brilliant.

Urticaria loses its element of itching shortly after the use of salicylic lotion.

Furunculosis.—In this affection the author knows of no other drug which will destroy the cause of the disease, that is, the staphylococcus pyrogenes aureus. He has had very favorable results from a six to ten per cent. plaster or mull, but it may be used as an ointment. The principal point made is that the drug should be of the purest quality. He used Scheering's (?) preparation, though Merck's is well spoken of. Inferior makes are accountable for the bad results others have had.

Dermatitis herpetiformis. — In one case the drug proved the best remedy the patient had tried.

Lichen planus was found to recover much more rapidly than under Unna's sublimate ointment. The lotion removes the itching and, later on, removes the scales.

Three and four per cent. solutions are here necessary. No arsenic or other internal remedy was employed.

Eczema of all varieties was benefited, and eighty-six cases were treated by it. One-half per cent. was used, to begin with, in pustular eczema and eczema madidans. In infiltrations from six to ten per cent. plasters or mulls are recommended.

Acne, of which there were fifty-six cases, was much benefited by a three per cent. alcoholic solution diluted to one-half per cent. to begin with.

Impetigo contagiosa is cured in ten to twelve days with the paste or gutta-percha solution.

Callosities, clavus, and *verruca* are softened in from twenty-four to forty-eight hours if adhesive plaster be applied over the acid. Papillary excrescences must be subsequently scraped out thoroughly or they will return. The corn will naturally return if the faulty boot be not remedied and pressure removed.

Pruritus of extremities, and pruritus ani of years' standing, was cured by lotions and mulls.

Tinea circinata and tonsurans.—For these it is highly recommended, and regarded superior to Taylor's four per cent. solution of sublimate in myrrh.

Dr. Pye Smith, of London, related a few personal cases and the success he has had with

SALICYLIC ACID IN HYPERTROPHIC GROWTHS

of the hands and other parts. He has found it excellent in removing epidermic accumulations. In ichthyosis, however, it is only of temporary benefit. Furunculosis does not depend upon poorness of the blood but upon local contagion, hence the benefit of salicylic acid. He approves of hardening the surrounding skin at the same time, and for this purpose a rather strong lead-lotion is used. He has also tried salicylic acid in lichen planus with benefit. Dr. Smith then made a few very complimentary remarks about American dermatologists and the favorable impression his countrymen in England had received of the work done in recent years on this side of the water.

Dr. Bulkley had found salicylic acid a great boon to ladies who suffered from excessive and offensive perspiration in the axilla. He prescribes it as a ten per cent. powder, mixed with starch and oxide of zinc. In eczema he thought great care should be exercised, as inflammation might be started up. In papular eczema he had found it a valuable addition to other ointments. In favus he had found it of value in an oily mixture, well rubbed in after epilation. In seborrhœa of the scalp it may prove too drying.

Dr. Fox said castor-oil was the only fixed oil with which it would readily mix. He uses it in a two per cent. solution in eczema, etc.

Dr. Van Harlingen had used it in all the common skin diseases mentioned. In eczema of the leg he applies it in glycerine and zinc oxide and puts on a wet two-tailed bandage from the toes to the knee.

Dr. Bronson thought that as a remedy by itself the drug had its limitations of usefulness. In most cases it is only a preparatory agent for other methods of treatment. The only class of cases in which it is curative are those where it acts as a germicide. In pityriasis and seborrhœa sicca, with accumulations of dead epithelium, it is of value in removing the débris.

Dr. E. B. Bronson, of New York, read a paper upon the use of a new remedy,

ANTHRAROBIN,

in dermatological practice. The drug was first introduced by Liebermann, a Berlin chemist, and recommended as a substitute for chrysarobin and pyrogallic acids, being, like them, a powerful deoxidizing agent. It is a yellowish-white, granular powder, sparingly soluble in chloroform and ether, and readily soluble in alcohol and weak alkaline solutions. It mixes readily with fats to form ointments. Behrend has had satisfactory clinical results from its use in psoriasis, herpes tonsurans, etc. Dr. Bronson has used the new remedy for the past few months, and tested its virtues in a variety of skin affections, using, as a rule, a ten per cent. ointment in vaseline. In eight cases of generalized psoriasis apparent cure took place in about a month. In one case remaining under observation for a few weeks, some guttate spots returned upon the back. The staining produced upon the skin is much deeper than that from chrysarobin, but does not diffuse itself over the surrounding skin as is the case with the latter drug. Scarcely any irritation was produced. In eczema a slight smarting sensation was produced at first. The twenty per cent. ointment did cause smarting. In one case of general eczema its use was abandoned because of the itching complained of. A case of eczema seborrhoicum of many years standing, upon which a great variety of treatments had failed to do more than ameliorate the condition, was much improved after a few days' use of the ten per cent. anthrarobin tincture. Little or no anti-pruritic effect was noted, and no opportunity occurred to try it upon parasitic diseases. The remedy is believed to have parasitic as well as keratoplastic properties, and there is reason to hope that the new remedy may render considerable service.

Dr. Heitzmann thought that anthrarobin had all the disagreeable qualities of the drugs it was intended to replace without having any advantage over them.

Dr. Morrow said his observations had been confined to the cases reported by the reader. The action of the drug had seemed to him to be limited and localized, and no essential difference between it and the drugs of the class to which it belongs were apparent, still the drug might have a future.

Dr. R. B. Morison, of Baltimore, then read a paper upon

PERSONAL OBSERVATIONS OF SKIN DISEASES IN THE NEGRO,

calling attention in a very practical way to the differences which exist between dermatoses in this race and in those of Caucasian origin.

Tables were presented of five hundred cases of skin disease in the negro, covering a goodly variety of affections. Dr. Morison having about fifty per cent. of negroes in his public practice enjoys an excellent opportunity for observation. The skin of the negro he has found less sensitive to heat, poisons, irritants, etc., and seems less liable to skin diseases of a severe type than the whites. The skin of the black is, histologically, more coarse and thick than that of the white. More dense fibres are found. The epidermis is thicker, and slightly yellowish in color. There is no appreciable difference in the thickness of the pigment layer between the true black and the mulatto. Fewer elastic fibres are found in the negro skin, but more subcutaneous adipose tissue.

The table spoken of is divided into those who were true blacks and mulattoes, because the author found that the nearer the color approached to white the less difference is noted in the lesions.

Acne is the first disease on the list, and has only nine cases, all in mulattoes. A corresponding table of five hundred cases in the white. collected during the same time, shows thirty-nine cases. Only one case of acne in a true negro has been observed by the author. No case of rosacea or coachman's nose has been seen.

Ainhum is a disease of the negro race, and the two cases in the table were both in black negroes. One had lost the little toe of one foot, and that of the opposite side was diseased.

Chancre was found to be more indurated than in the white. The only extra-genital primary lesions found were upon the lips, and two cases are given.

Chilblain is commonly encountered.

Chloasma is frequent in the negro. Few apply for treatment. It appears as a loss of pigment, causing a yellowish spot on a dark background. Treatment must be reversed and pigment produced instead of being abstracted.

Elephantiasis arabum usually follows syphilis; two such cases are recorded.

Erythema multiforme appears in small or large spots without redness, but attended with much burning and itching.

Erythema nodosum was seen in two mulatto women. More itching and less pain seemed to exist than in the white.

Acute eczema is less common and less severe. Only nineteen per cent. of cases are recorded, while the "white" table gives thirty per cent. In the female, eczema occurs mostly upon the hands. Infants have a modified milk crust, approaching moist eczema. Chronic eczema in the mulatto does not differ from that of the white.

Favus is rare in the negro. Furunculosis appears infrequent, while herpes facialis is common. In herpes zoster the pain seems less severe and less prolonged, but there is itching. Keloidal growths sometimes follow the eruption. Impetigo contagiosa is indistinct and not characteristic.

Keloid is common, and in two of the three cases seen, resulted from small-pox. In the mulatto it is almost as rare as in the white.

Lupus is rare, although the negro is prone to tuberculosis of the lung.

Molluscum contagiosum gave one case upon the genitals. The contents of the tumors was darker than in the white.

Pediculi capitis appears to be quite rare, and the lesions produced by pediculi vestimenti are slight. The bite of the mosquito and cimex lectularius produces little effect upon the black skin.

Pruritus is much complained of, and itching is quite common in the eruptions of syphilis.

In psoriasis the crusts are yellowish and less shiny; only six cases are given. After the lesion is cured a whitish spot remains for a time. It is readily cured.

Scabies is not very common it would appear, and the lesions less severe than in the white.

Seborrhœa capitis is common.

Syphilis offers many points of difference, besides the pruritus mentioned. The incubation period appears shorter; the chancre is larger and more indurated; phymosis is more common; glandular enlargements more pronounced and more prone to suppurate. The macular eruption may be easily overlooked. Tertiary lesions are commonly noted. Thus the disease is more prompt in its first stage, more violent in its second, and more obstinate in its third.

Tinea tonsurans is common, and the scales appear white.

Urticaria in the black is a mild disease, the wheals are not much elevated, the centre is lighter in color.

Verruca is common, they are usually large, but papilloma appears less frequent than fibroma.

Dermatitis venenata has no case reported in the table, but Dr. Morison has learned that it does occur and is very itchy, but the eruption is slight. The pigmentation of the skin is regarded as the prime factor, according to the author, in causing these diseases in the negro to differ from the same affections in the white. In the discussion Dr. Heitzmann asked if the reader meant that in chloasma there was really a lessening of pigment. He considered chloasma as always referring to an hypertrophy of pigment. If there were a diminution he would regard it rather as a leucoderma. He also considered it remarkable that there should be such itching in syphilitic lesions. Dr. Morrow said he had always found difficulty in making a satisfactory diagnosis, especially in erythematous conditions.

Dr. Bulkley has seen some true cases of chloasma in the negro, but vitiligo was much more common. In chloasma the patches are darkened. Itching is a common symptom in the negro, and an accurate diagnosis aside from that of pruritus is difficult.

Dr. Shirwell was surprised that no cases of lupus were contained in the tables.

Dr. Fox was impressed by the fact that no cases of the acute exanthemata were recorded. In suspected scarlatina the early diagnosis depends upon the throat lesions and the fever course, as the skin lesions are not to be made out, but at the period of desquamation the smooth lustre of the black skin is lost, the surface turns gray and presents an appearance as though pepper had been sprinkled over the body, and parents called this, in fact, the peppery skin.

Dr. Frederich, of Washington, reported that in his practice the same run of cases had been noted as those mentioned in the paper, and his observations coincided with those of the reader. He had recently had two cases of elephantiasis arabum, one being a double case. He had found much syphilis in the negro race.

Dr. Robinson had observed a case of chronic pemphigus and a few of ringworm. He did not think that a sufficient number of cases had yet been collected to serve as a base for just conclusions.

Dr. Atkinson has long felt that a chapter on this subject was requisite, and congratulated Dr. Morison on starting this series of observations. He himself has had a large experience in the treatment of negroes and agrees that acne is uncommon, but calls attention to a condition in young negroes who shave closely. A pustular folliculitis of the beard, each pustule penetrated by a hair, but no infiltration of the surrounding skin and having no tendency to become a typical sycosis of the nonparasitic variety. He has found fifty per cent. of young negroes who shaved closely to be affected. They do not usually apply for treatment, and he has no particularly efficacious treatment to recommend.

He, too, has noted a greater degree of induration in true chancre, and a marked tendency to the development of periadenitis producing great masses in which the outline of the glands is lost; suppuration is common, but not like that of chancroidal bubo, pockets of pus forming and the inflammation involving the periglandular tissue. Scabies, on the contrary, he has frequently observed.

In closing, Dr. Morison said the chloasma noted was not light enough to class as vitiligo, and considered it due to uterine disturbance. Pediculi vestimenti was common. In the Southern schools it was taught that, differing from the white races, the negroes did have pruritus associated with syphilitic eruptions.

AMERICAN ORTHOPEDIC ASSOCIATION.

Tuesday, September 18th—First Day.

After a few remarks by the President, Dr. N. M. Shaffer, Dr. V. P. Gibney, of New York, read a paper entitled

REPORT ON THE TREATMENT OF CLUB-FOOT BY MEANS OF THE THOMAS WRENCH, OR "T. T."

The wrench presented was a modification of that of H. O. Thomas, of Liverpool, and consisted of a modified monkey-wrench, with arms jutting out from the side, which are made to grip the astragalus and plantar arch by a screw movement, and then by the leverage of the handle the foot is twisted and forced into shape. He uses the wrench with or without etherization, and alone, or as an aid to tenotomy. The foot was to be corrected at once if possible (in congenital cases), but the operation should be repeated again, or as many times as may be necessary. Twelve cases were reported in detail, which, after having been treated by manual wrenching and Knight's brace for long periods without a cure, gave, under the use of the above treatment, good results. As after-treatment a shoe, built up along its outer border, was advised. In the older cases two or three operations were necessary; but in the younger usually one sitting was sufficient. Five paralytic cases were not difficult to manage.

Dr. Ridlon, of New York, showed a wrench, also a modification of Thomas', to be used for the same purpose, and as an osteoclast in a badly united Colles' fracture. It differed from the wrench of Dr. Gibney in having the grip-rods straight and in having a spring-grip which could be instantly released by pressing a trigger. It was modified from a "Utility Wrench." The subject was discussed by Drs. Bradford, Steele, Moore, Vance, L. H. Sayre, Whitehead, Hodgen, Ryan, and Shaffer.

Dr. H. Hodgen, of St. Louis, read a report on

MORTON'S METHOD FOR THE IMMEDIATE REDUCTION OF CLUB-FOOT.

A detailed account of eight cases was given, and the following deductions were drawn:

1. Tenotomy for equinus should be made first, and the deformity at once reduced.

2. Immediate reduction of the deformity is the proper procedure. Saves time and pain, and the correction is more certain.

3. Can be used in all cases with safety, but has no advantage over hand pressure of the surgeon in young subjects when the tissues are soft.

4. There is no need of preparatory treatment of the tissues by poulticing.

5. The force should be applied inward, downward, and slightly forward, until the tissues are felt to give way.

6. Plaster-dressings applied with the foot in the position of valgus, and allowed to remain on for two months.

7. The bursa will have nearly disappeared when the cast is removed, and they are not, as a rule, tender.

8. The use of the club-foot shoe for some time, in which pressure can be made in the direction of the crushing force.

9. A marked rise of temperature is not to be expected, and when this and pain are present we must look to the plaster as the cause in a large percentage of these cases.

Dr. E. H. Bradford, of Boston, then read an

ANALYSIS OF TREATMENT OF SEVENTY CASES OF CLUB-FOOT.

He said that the clinical memoranda should include the record of imperfect results and of failures, and if possible an investigation of the causes of failure. A detailed statement of the pathological anatomy of club-foot is unnecessary, as it has been thoroughly investigated and admits of no dispute. As it is well known that there is not only a misplacement of the foot, but also always a distortion of the bones of the foot and shortening of some of the ligaments and soft tissues, including, of course, the tendons. The chief distortion is in the astragalus, the neck and anterior facet being inclined to the side. The treatment requires:

1. A rectification of the misplaced bones.

2. A retention in a normal position until the abnormal facet of the astragalus renders the pressure of new position normal. An examination of the current literature of the subject shows much diversity of opinion as to methods.

The following questions in regard to the treatment are at present unsettled:

1. In what cases is it advisable to correct and treat by mechanical means alone, without the help of any operative interference, even tenotomy.

2. When is tenotomy advisable?

3. Can severe cases be entirely corrected and cured without tarsal resection, or osteotomy?

4. Is tarsal resection, or osteotomy, a justifiable operation?

These questions are answered by the tables of cases, thus:

1. That the cases of infantile club-foot can, as a rule, be thoroughly and efficiently treated without tenotomy, by mechanical correction and mechanical retention alone.

2. That in older cases tenotomy aids the correction, and is not injurious to the permanent result.

3. That resistant cases of the severest type can be corrected without tarsal osteotomy.

4. That in some cases of resistant club-foot torsal osteotomy is needed for perfect rectification, and is not only justifiable, but may be indicated in exceptional instances.

Dr. N. M. Shaffer, of New York, then exhibited a brace for the treatment of varus, applied to the outer side of the leg and foot, and intended to *pull* the foot into position.

In the discussion which followed upon the papers of Drs. Hodgen and Bradford, remarks were made by Drs. Moore, Willard, Vance, and Steele.

Dr. George W. Ryan, of Cincinnati, reported a case of

REFLEX VALGUS

in a boy ten years old. The condition appeared three or four weeks after a reported slight sprain. There was no swelling or pain, and the only symptom presenting was the unusual contracture of the peronei group, which was intensified if it were touched, or any attempt made by means of apparatus to correct the deformity. There were no spinal symptoms, and no other hysterical symptoms; the patient resented treatment, and wished to resume his accustomed play. The treatment which was prescribed was not followed, and no change in the condition had occurred when last heard from, some eight months after he came under observation. The paper was discussed by Drs. Gibney, Vance, Judson, Sayre, and Shaffer.

Dr. A. B. Judson, of New York, then read a paper entitled

A PRACTICAL POINT IN THE TREATMENT OF POTT'S DISEASE.

The author believed that in the unsatisfactory state of the treatment of Pott's disease, it would be well to judge of the efficiency of mechanical treatment by the impression made by the apparatus on the skin covering the projection. He thought the object of treatment was threefold: to fix the diseased bones, to transfer pressure from the bodies to the processes, and to reduce the deformity. If the skin near the summit of the projection becomes thickened and callous, which it does without discomfort if the pressure is carefully increased from time to time, it is to be considered that the apparatus is acting as it ought to, and when the greatest pressure is made compatible with the integrity and comfort of the skin, the apparatus has reached the limit of its efficiency. This rule is less applicable to the treatment by suspension and the plaster-of-Paris jacket. He would not say a word against the plastic apparatus. In the hands of the general practitioner plaster-of-Paris gives relief to many cases which would otherwise have no mechanical treatment. But the orthopedic surgeon can do better by the use of tractable steel modified to fit the varying needs of the patient with the mechanical skill which belongs to practitioners of that class. The author further agreed with Dr. Shaffer in the importance of avoiding, as much as is practicable, the application of water to the skin which is subject to pressure.

The paper was discussed by Drs. Moore, Ridlon, Whitehead, Steele, and Shaffer.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Tuesday, September 18th—First Day.

Dr. R. P. Lincoln, the President, congratulated the fellows of the Association upon the gratifying results of the ten years of harmony and good-will that they have enjoyed as fellow-workers, and upon the appreciation of the same by the profession at large as the reward of their conscientious work and persevering investigations in behalf of science. The Tenth Annual Congress having been declared open, the first paper was read by Dr. G. M. Lefferts, of New York, on

IMAGINARY LINGUAL ULCERATION.

It is, however, very real to the sufferer, on account of the severe pain and distress, and proves most puzzling to the physician as to etiology, pathology, and treatment. It occurs impartially as regards sex, and usually between the ages of thirty-five and fifty. The most marked symptoms are darting intermittent pains along one side of the tongue, usually the left. They extend from the base to the middle third or tip of the tongue, following the line of demarcation between the rough dorsum and smooth mucous membrane below.

These pains are aggravated by talking, eating, or in any way using the muscles of the tongue and pharynx, also by heat, cold, or local irritation of any kind. The trouble is not confined to hypochondriacal or hysterical subjects, but exists as a painful reality where the patient enjoys robust health. Unless irritant applications have been used, physical examination reveals nothing. The author has seen many cases where no appreciable cause could be found, although the wearing pains had caused morbid fears of cancer, syphilitic ulceration, etc., resulting in thorough demoralization of the patient. Experience has taught no satisfactory treatment. Electricity, cocaine, and hypodermics give temporary relief only.

Dr. Bosworth considers local irritation, inflamed papillæ, and hysteria most frequent causes, but is ignorant as to the pathology.

Dr. Ingals had found rheumatism and excessive use of tobacco in many cases the cause; arsenic proved a useful remedy in his experience.

Dr. Frank Donaldson, of Baltimore, reported

A CASE OF SUBGLOTTIC STENOSIS OF THE LARYNX TREATED BY DILATATION.

Mrs. R——, aged twenty-four, married, with four children, and healthy from childhood, awoke one morning with hoarseness from a slight cold. As the throat was not sore, but little attention was paid to it. Months later the voice became stridulous, and in spite of active treatment breathing became more and more difficult, especially at night. Later she was sent to the author as a severe case of emphysema. The slightest exertion caused alarming dyspnœa. He found smooth, well-defined membrane below the vocal cords, and almost including the narrow space encircled by the cricoid cartilage. Could find no trace or history of syphilis in either husband or wife or their families, nor of any injury to her larynx. A course of treatment by careful dilatation caused gradual disappearance of membrane, leaving only a very narrow ring at the site of its attachment. To be successful in these cases requires patience and perseverance on the part of both doctor and patient as well.

Dr. Carl Seiler, of Philadelphia, reported a case of

STENOSIS OF THE LARYNX AND TRACHEA.

This case, a boy aged two, had persistent hoarseness, following a cold, which became more marked during the following year. Found health excellent, and larynx normal, with the exception of small papilla on posterior portion of left vocal cord. Removal was delayed. Saw the case five years later, after tracheotomy had been performed. Larynx was so completely filled by a mass of papillomatous growth that no air could be forced through it. The tracheotomy tube had caused deep ulcerations, and was embedded in a mass of vascular granulations. The boy had a curious method of filling the upper respirative cavities with air, and by forcibly expelling it he could phonate intelligibly, using the pillars of the larynx and tonsils instead of the vocal cords. The removal of the growth was facilitated, during laryngotomy, by using the fingers of the left hand in the mouth for pushing it downward through the larynx. Although stricture had been left by ulcerations about the tube, the patient has been gradually gaining in power of voice and breathing space. He still wears a tube.

Dr. J. Solis-Cohen, of Philadelphia, presented a specimen of

STRICTURE OF THE LARYNX WITH EXTENSIVE CICATRIZATION, FOLLOWING ULCERATIVE TUBERCULOSIS.

An apparently healthy woman, aged forty-five, first noticed slight sore-throat after taking cold. For several years the symptoms increased in severity, until she became alarmed at loss of voice and difficulty in swallowing and breathing. Found uvula and epiglottis gone, and pharynx much deformed by cicatricial contractions. A thick, dense, cicatricial mass partly filled the larynx, connecting ventricular band and ary-epiglottic fold with those of the opposite side. A portion, half an inch thick, was cut out, so as to admit tubes for dilatation. Bacilli and giant-cells were found in it.

The case followed the usual course of destructive ulceration, etc., so that the larynx was presented.

During discussion, the majority of the members did not speak in favor of dilatation, having experienced unsatisfactory results. Where temporary benefit had resulted, the tubes could not be abandoned because contraction would again give trouble. Dr. Rice considered O'Dwyer's tubes useful to control hemorrhage, when operating within the larynx, by keeping blood from the trachea, and a substitute for preliminary tracheotomy.

Dr. Edgar Holden, of Newark, N. J, read a paper entitled

A POSSIBLE SUBSTITUTE FOR TRACHEOTOMY AND INTUBATION IN CERTAIN CASES.

Under this modest heading Dr. Holden read an excellent paper descriptive of a new and safe method of overcoming laryngeal obstruction. A short description was first given of its numerous causes, and of the sudden emergencies that call for the utmost haste in giving free access of air to the lungs as the only means of saving life. A long list of recorded mistakes, accidents, and dangers attending intubation was accompanied by a somewhat similar record in the history of tracheotomy.

The ingenious instrument he presented is obviously so designed as to render most of these unfortunate complications impossible, while operating with greater ease and rapidity. Thin silver blades are introduced through the crico-thyroid membrane and passed between the vocal cords. These are separated by pressing together the two short external extremities, which are at right angles to the rest of the blade and united to each other by a hinge where they rest in the wound. Pressing the outer ends together separates the inner blades between the vocal cords.

Advantages: Easy of introduction and removal; cannot be displaced; breathing through natural passages; no interference with swallowing, etc. Also well adapted for removal of foreign bodies in the trachea.

A drawing was next shown of a very long silver tracheotomy tube, designed by A. Gouguenheim, of France, the lower end having flexible spiral. Introduction easier and injurious pressure avoided.

Dr Clinton Wagner, of New York, presented a communication entitled

RESIDENCE IN HIGH ALTITUDES AS A MEANS OF CURE FOR LARYNGEAL PHTHISIS.

After discussing the comparative advantages offered by the various mountain health-resorts, the reputation of many was substantiated by reports and statistics. Among those thus favored were Colorado Springs, Denver, Lake Tahoe, Pueblo, and various resorts in the mountain-chains of our own coast. Reports from resident physicians were read concerning permanent cures of those under careful daily observation. Cases were mentioned that had been under the author's personal care, and recovered, although destructive ulceration had commenced. Best results where rarefied air is pure and dry, with plenty of sunshine, and admitting of the greatest number of hours in open air, with good food and a few home comforts. Thirty-three per cent. of phthisical patients have laryngeal complications, which are especially benefited by high altitudes, if in incipient stage and before ulceration begins.

During the discussion of the paper, **Dr. Glasgow** said that a large percentage of laryngeal complications were not tuberculous, while in other cases tubercular infiltration appeared in the larynx before the lungs were involved. Extreme altitudes he found disastrous where there were any laryngeal complications; moderate altitude, 3,000 to 4,000 feet, safer, till improvement of the larynx warrants their making the change.

The unfavorable conditions in Switzerland are due to sudden changes in temperature, fog, and dampness. Phthisical cases are hopeless unless an early start is made. Improvement reported in more advanced cases means that the disease is at a stand-still, not cured while they remain, and will return on leaving these favorable localities.

Dr. John N. Mackenzie, of Baltimore, read a paper on

A HITHERTO UNDESCRIBED NEUROSIS OF AURAL APPARATUS, RESEMBLING CORYZA SYMPATHETICA.

Mrs. A——, aged forty-two, has for many years had an affection of the ear resembling the catarrhal condition of the nasal cavity found in hay-fever. Regularly, about June 1st, it attacks one ear only, alternating yearly, as a rule, from one to the other. Begins with itching along the external canal, followed by pain and swellings that nearly close the canal but contain no pus. Canal very sensitive and resents applications. Then soreness is felt in the throat, about orifice of Eustachian tube; pain on swallowing as inflammation extends toward middle ear; tympanum congested. Nothing modifies its course, which is four weeks. Discharge is free, and there is temporary deafness. No trouble appears in throat or nose. Suddenly disappears.

Possibly sympathetic and similar to the inflammation of nasal mucosa caused by irritation of spheno palatine ganglia.

Dr. D. Bryson Delavan, of New York, presented a communication entitled

FURTHER INVESTIGATION AS TO THE EXISTENCE OF A CORTICAL MOTOR CENTRE FOR THE HUMAN LARYNX.

The paper was one of great scientific interest, embodying the result of a large amount of original research and careful investigation, at the dissecting table, of the brain-lesions in those who had suffered from laryngeal paralysis.

Dr. E. J. Moure, of Bordeaux, reported a case of

ACUTE ŒDEMA OF THE SUB-EPIGLOTTIC REGION AND LOWER PHARYNX IN A DIABETIC PATIENT.

The case presented the usual symptoms of œdema in this locality, but there was no apparent cause. It disappeared in three days. Examination of urine showed sp. gr., 1.039, and contained seventy grains of sugar. Considers it the cause of this laryngeal œdema.

Dr. D. N. Rankin, of Allegheny, Pa., read a paper on

PARASITES INHABITING THE HUMAN NARES,

reporting a number of cases.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Tuesday, September 18th—First Day.

Dr. A. L. Loomis, of New York, delivered the

PRESIDENT'S ADDRESS.

The profession has been stimulated by the work of this Society in climatology. The climatology of old age will chiefly be considered in the address. The body declines, while the mind keeps its vigor much longer, and therefore, if the body be properly taken care of, much mental work may be done, and often of a high order. An important hygienic law is, that the brain be stimulated by pleasurable occupation; also proper food and plenty of fresh air should be available; but it is important that the extremes of temperature, either of heat or cold, should be avoided. The ancients paid great attention to the hygiene of old age. Certain rules should be observed in choosing a climate for old persons. 1. Healthy old age is best passed in moderately warm climates; changes, however, are of advantage, and it is not necessary that old persons should always remain in one locality. 2. They should live in a climate where a great part of the time can be spent out-of-doors. 3. Well-cooked food is of great importance to the aged; it should be simple and easily digested.

Diseases occurring at other times of life may present special characteristics in old age, and we have also diseases, due to degeneration of tissue, peculiar to this time of life. We must consider these facts in choosing a climate for old age. High altitudes are not usually safe for the aged, and it is never safe for them to pass suddenly from a low to a high altitude when they are suffering with phthisis pulmonalis. Localities like Nassau, Cape May, or Newport are advantageous in such cases. Changes of climate are also a prophylaxis against the development of phthisis, and this should be more fully recognized than it is. A person recovering from an acute attack of pulmonary trouble may sometimes escape the development of phthisis by a timely change of climate. Gout and rheumatism, so common to the old, may often be avoided by a trip to California or Florida. Cystitis is often aggravated by a cold, damp climate and is benefited by a change to a warmer climate.

Dr. S. A. Fisk, of Denver, read a paper on

A STUDY OF THE CLIMATE OF COLORADO AS APPLIED TO THE ARREST AND CURE OF PULMONARY DISEASE.

So many cases of the cure or arrest of disease have come under observation that he cannot refrain from making some statements on the subject. On account of there being no large bodies of water on the eastern side of the mountains in Colorado, and the drainage being mostly subterranean, the climate is extremely dry; the elevation of the region resorted to by invalids varies between three thousand and eight thousand feet or more, so that the elevation may be regulated by the needs of the patient. The effects of elevation, of the small amount of humidity, of the large number of sunshiny days, in Colorado, were dwelt upon at length. In the winter months the variations in temperature are extreme, and in certain situations in the summer the heat is often great.

The velocity of wind in Denver, contrary to the frequently received opinion, is not often very great; and in this Denver will compare favorably with the Connecticut Valley. The dust-storms are at times, however, sufficiently severe to be detrimental to invalids if exposed to them. Fogs are almost unknown. He questions if elevation is any assurance of the absence of germ-life. Putrefaction and decay may be found where other appropriate conditions are present, anywhere in Colorado.

Dr. S. E. Solly, of Colorado Springs, read a paper on

INVALIDS SUITED FOR TREATMENT AT COLORADO SPRINGS.

The situation, area, population, and excellent drainage of Colorado Springs were spoken of. The effects of the elevation on the skin, the circulation, the respiration, the digestion, the nervous and muscular systems, were considered. He mentions the danger of elevation in cases of fatty degeneration of the heart muscle.

In persons under thirty years of age, with dilatation of the heart, the greatest caution should be used to live carefully and not to take too much or too violent exercise. When the heart is normal, although its action is at first increased, after a time it invariably returns to its normal condition. He recommends the place for arresting threatened tuberculosis; fibroid phthisis also does well. Renal complications make the change to Colorado risky. Moderate dilatation of the heart in the young is not a positive contra-indication.

Dr. R. G. Curtin, of Philadelphia, read a paper entitled

IS CLIMATE AN ETIOLOGICAL FACTOR IN GRAVES' DISEASE?

He has tabulated over seventy cases, and has studied the subject for twenty years. He found forty cases in fifteen families, and after carefully investigating has concluded that the disease is hereditary. A large proportion of his cases came from Alsace and Lorraine, and he thinks that elevation has an influence on the development of the disease, which might otherwise have remained quiescent, and he believes he has seen instances of this among persons residing in the Alleghany Mountains.

Dr. Geddings mentioned a case of goitre which became severe when taken to a considerable elevation.

Dr. Fisk remarked that the cases he has seen do not lead him to think that elevation is injurious to goitre.

Dr. P. H. Kretzschmar, of Brooklyn, read a paper on

HEALTH-RESORTS *versus* INSTITUTIONS FOR THE TREATMENT OF PULMONARY CONSUMPTION.

We are far behind Europe in this matter. We have not utilized our mineral springs as we could do, considering the number and value of those we have. He strongly advocates the advantages of sanitariums where a careful supervision can be had over the patients. He considered somewhat fully the *régime* adopted in various institutions and the imprudences indulged in at health-resorts.

Dr. Loomis said that he did not believe that health-resorts were of much benefit to consumptives unless they were under the care of a competent physician. All his patients that are sent to the Adirondacks are obliged to give themselves up entirely into the hands of their physicians.

Dr. Solly considered the regulation of the daily life of the patient as the most important part of the treatment, but opposes collecting a large number of patients together.

AMERICAN PHYSIOLOGICAL SOCIETY.

Tuesday, September 18th—First Day.

The meeting of the Society was called to order at noon by the President, Dr. Henry P. Bowditch, of Boston, Mass.

Dr. W. H. Howell, of Baltimore, read a paper entitled

THE ORIGIN AND REGENERATION OF RED BLOOD-CORPUSCLES.

The paper gave an account of experiments made chiefly upon the cat, the object of which was to trace the development of the red blood-corpuscles and the organs which take part in their manufacture, both in the fœtus and the adult. It was found that of the organs which successively take up the function of making red blood-corpuscles the first to take on this activity was the liver, the next the spleen, and the last the red marrow of the bones. At the third or fourth week after birth the liver and spleen no longer give evidence of producing red corpuscles, and from that time on, in the normal animal, the function is confined to the red marrow of the bones. It was found, however, in the adult cat, that the spleen could be made to resume this function at any time by bleeding the animal severely. Under these conditions, apparently, the marrow was no longer equal to the task of furnishing the new corpuscles, and the spleen also took part in the process. Experiments were made upon normal animals and upon animals which had been bled one or more times, with reference to the regeneration of the red corpuscles in the marrow of the adult. The methods used were the examination of the fresh marrow with methyl green, sections of the hardened marrow stained with hæmatoxylin, eosin, and saffrain, and also observations upon the living marrow, examined in the animal's own serum upon a warm stage. The conclusions reached were as follows: The nucleated red corpuscle of the marrow in the adult is derived from a colorless nucleated cell found in the marrow, and shows the same characteristics, with the exception that it contains no hæmoglobin. This cell multiplies by direct division, and hæmoglobin becomes developed in the cell-substance of its offspring, forming thus the nucleated red corpuscle. These are also capable of reduplication by indirect division as long as the nucleus shows a reticular structure, but when this is lost and the nucleus stains deeply and uniformly with methyl green, it is no longer capable of karyokinesis. Its nucleus is then extruded, and there is left a non-nucleated red corpuscle, which later becomes a bi-concave red corpuscle of the circulation. The chief point of the paper was the evidence brought forward to show that, in the transition from the nucleated red corpuscle to the non-nucleated form, the nucleus escapes bodily, and does not disappear within the cell by a process of disintegration. The hypothesis was made that possibly these escaped nuclei getting into the circulation give rise to the blood-plaques.

Dr. H. C. Wood called attention to the fact that in anæmia one finds hypertrophy of the bone-marrow, while, if the lack of red blood-corpuscles is dependent upon under-production, one would expect to find the marrow atrophied.

Dr. Howell replied that there might well be such a vast destruction of red blood-corpuscles at such times, that even the hypertrophied marrow is unable to supply the loss.

Dr. Wood said that in malaria the marrow was generally not hypertrophied.

Dr. William Welch stated that he was at Cohnheim's laboratory at the time that he was studying the condition of the marrow of the bones in anæmia. That he found nucleated blood-corpuscles in all forms of diseases in which anæmia was a prominent condition—in cancer, Bright's disease, phthisis, etc. When anæmia was very marked very many nucleated corpuscles were found.

Dr. Welch thought that at such times the marrow was stimulated to increased activity, but that it was unable to keep pace with the destruction of the red blood-corpuscles. In pernicious anæmia cells are found containing red corpuscles in all degrees of disintegration, and it is probable that they may be responsible for the loss of red corpuscles. The organisms found in malaria which resemble amœba superficially, are really quite different, and ought not to be confounded with them.

Dr. Hare suggested that it was possible that in the diseases mentioned the young cells were manufactured by the marrow, but failed to mature.

Dr. Bowditch urged the advisability of extending the research to the lower animals. The conditions which exist in the fœtus might well be found in adult fishes. He inquired of Dr. Howell whether he had obtained any facts concerning the length of life of the red corpuscles, and, obtaining a negative answer, suggested that the remnants left by the nucleus when it passed out of the cell might be used to distinguish the corpuscle, and be of aid in this study.

Dr. Howell said he had met with nucleated cells for a week after the animal had been bled.

Drs. Henry Sewall and Myra E. Pollard presented a communication entitled

THE RELATIONS OF DIAPHRAGMATIC AND COSTAL RESPIRATION, WITH PARTICULAR REFERENCE TO PHONATION,

which was read by Dr. H. N. Martin.

The paper consisted of two parts, the first of which discussed the relations existing between the different groups of respiratory muscles, and called attention to the fact that they are frequently employed in opposite phases of inspiration and expiration, a class of phenomena which was referred to as complementary movements of respiration.

The writers cited experiments on Indian, Chinese, and civilized women, to show that costal respiration is not, as is generally supposed, peculiar to women, but is the result of the tight clothing worn by most civilized women. The normal respiration of women differs but little from that of men who lead sedentary lives.

They stated that diaphragmatic respiration is most important during quiet when the blood is in the abdominal vessels, for by pressing on the abdominal contents, as it contracts, the diaphragm forces the blood and lymph out of the abdominal cavity toward the heart, and so greatly furthers the circulation. When the blood is in the muscles during violent exertion, costal respiration is most active, both because it favors the aspiration of the thorax, and because it enlarges the chest most, and so gives the needed supply of air.

They pointed out the value of diaphragmatic respiration in changing the air in the lower parts of the lung, and showed that movements of the bottom of the lung must aid in mixing the air throughout the air-passages.

Experiments with the spirometer proved that the vital capacity was greater by costal respiration, which corresponds with the fact that respiration is always costal when there is urgent need of air.

The writers lay great stress on the advantage to man, and more especially to the lower animals, of movements of the chest-wall, which will mix the air in the lungs when the glottis is closed. Coughing, sighing, sneezing, and laughing are complementary movements of respiration, rapid, extensive, and powerful, and they are probably of great use in mixing the inspired air. Complementary movements of the throat and flank of the frog when the glottis is closed have a similar importance.

The second part of the paper treated of

THE RELATION OF THE COMPLEMENTARY MOVEMENTS OF RESPIRATION TO VOCALIZATION.

The results already stated show that phonation by use of diaphragmatic respiration would most economically meet with the needs of the body. The power and quality of the voice depends not so much on the trembling of the vocal cords as on the sympathetic vibration of the air in the resonance chambers above and below the larynx. The function of the thorax as a resonance chamber seems, up to the present time, to have been disregarded, though of the greatest importance; for the chest even seems to have a selective resonance, so to speak, analogous to that manifested by the oral and nasal chambers. The experiments of the writers showed that the tension of the bounding walls of the chest influence the resonance, and that its fundamental note and overtones are altered by changes in the shape and size of the cavity. They found the ascent of the scale to be easier and the tones to be purer when the sound-producing air-current was driven by the contraction of the abdominal muscles and with a simultaneous inspiratory movement of the upper chest. A lower note could be reached, however, when the chest-muscles were the driving force and the diaphragm was progressively depressed.

By graphic methods the changes in the form of the chest and abdomen during quiet breathing and singing were studied. The results of these experiments cannot be well condensed. It was found that increase of the transverse section of the thorax and decrease of its vertical diameter elevated the pitch of its fundamental note, while the reverse conditions lowered it. Elevation of the chest during abdominal contraction is a real movement of costal inspiration, although the air is supplied from below rather than from above. The air is also drawn into the lower part of the chest when the diaphragm descends and the ribs collapse. Such movements favor the interchange of gases within the lung. A few experiments made to see whether during speaking a similar play of the diaphragm occurred, confirmed the conclusions already reached.

In conclusion, the writers state "that while the main vocal blast is supplied by the steady sweep of the diaphragm and the abdominal muscles, the accent which gives life to song and speech is accompanied and supported by a characteristic play of the chest and diaphragm, in which the rapid changes of the fundamental note of the great thoracic resonator adjust it anew for every note sent out from the vocal cords."

Dr. Bowditch expressed much interest in the complementary movements of respiration described by the writers. He said that, as far as he knew, there was great difference in the methods taught of managing the respiratory muscles in singing, and that this paper, and the exact methods of study which it ought to provoke, might well prove of the greatest service.

Dr. Martin expressed a doubt as to the effect which movements of the frog's throat could have over the interchange of gases within the lungs of the frog when the glottis was closed.

Dr. H. H. Donaldson, of Baltimore, then read a paper on

THE HISTOLOGICAL CHANGES PRODUCED IN GANGLION CELLS BY STIMULATION.

Dr. Donaldson said that, at his suggestion, Mr. C. F. Hodge, of the Johns Hopkins University, had undertaken a study of the spinal ganglia. As preliminary work, he teased the spinal ganglia of frogs, and in studying them found two cases where there were typical bipolar cells, such as are found in fish, besides cells with straight and spiral fibres, such as Beale has described, and cells with the ordinary T-process. There were found in addition many cases where the process of two cells united to form a single fibre corresponding to the stem of a T-process. Closely connected with this anatomical relation is the fact that there are from two to three times as many cells in the spinal ganglia as there are fibres in the posterior roots.

The special changes which are observed as the results of electrical stimulation of the ganglia, were obtained as follows:

The animals were all rendered reflex, curare or anæsthetics interfering with the reaction. In frogs, the proximal end of the cut ischiadic nerve, and in cats the proximal end of the nerves forming the brachial plexus, were stimulated electrically, and the ganglia belonging to these nerves examined; the stimulated ganglion on one side being compared with the symmetrical unstimulated ganglion.

It was found, when the cells were compared, that those belonging to the stimulated ganglia had smaller nuclei, the protoplasm was vacuolated and granular, and they stained more deeply. The shrinkage of the nucleus was from ten to thirty-three per cent. of its volume. That this is the direct result of stimulation is indicated by the fact that, in the case of one cat stimulated seven hours, it amounted to twenty-nine per cent.; while in another stimulated for one hour and forty minutes, a diminution of only twelve per cent. was found.

Dr. R. H. Chittenden, of New Haven, Conn., being absent, his paper was read by Dr. W. H. Howell,

ON THE PHYSIOLOGICAL ACTION OF URANIUM SALTS.

Dr. Chittenden's experiments were begun in the laboratory of physiological chemistry at Yale University, and they were addressed to ascertaining the physiological and toxical action of uranium salts. Results previously published had shown the writer that all the uranyl salts, with one or two exceptions, have a more or less marked inhibitory influence on amylolytic and proteolytic action. It was also found that uranyl nitrate, when 0.7 grain of the salt was given in divided doses, caused a rise of temperature and an increase in carbonic-acid excretion.

The object of the experiments described in this paper was to ascertain the effect of uranium salts on proteid metabolism; their toxic action and their influence on the production of glycosuria. The experiments were conducted with great care, and were fully described in the paper.

The collective results show that uranium is an irritant poison, and that it, like other metallic irritants, produces gastro-intestinal irritation of more or less intensity, resulting in most cases in a simple enteritis, but often becoming an acute catarrhal inflammation. As a poison it acts slowly, and one hundred and fifty milligrammes appears to act as vigorously as a gramme. In rabbits the first marked symptom is general weakness with loss of co-ordination, and occasional temporary paralysis of the locomotor muscles. Introduced into the stomach, it checks digestion. It increases proteid metabolism and the excretion of carbonic acid, and causes a rise of temperature. Its effect on nutrition is shown by rapid emaciation. The most marked lesion is seen in the kidney, where it produces acute parenchymatous nephritis. The large amount of albumen found in the urine shows how greatly the blood-vessels are involved. Small doses cause at first an increased quantity of urine, but toxic doses result in complete suppression. A short time after administration of the drug, more or less sugar is found in the urine; this generally does not come until after albumen has appeared. The production of glycosuria is a very characteristic symptom in uranium poisoning. The urine invariably contains large amounts of calcium oxalates, which also points to decided malnutrition and helps explain the marked emaciation so commonly seen. In cases where the poisoning became chronic, the nervous symptoms sometimes predominated, as was shown by loss of sight and power of co-ordination.

THE ASSOCIATION OF AMERICAN ANATOMISTS.

Monday, September 17th—First Day.

A meeting was held in the lecture-room of the Georgetown Medical College, on Monday, September 17th, for the purpose of organizing an Association of American Anatomists. Dr. Harrison Allen, of Philadelphia, was chosen temporary Chairman, and Dr. A. H. P. Leuf, of Philadelphia, temporary Secretary. The organization of the Association was effected, a constitution adopted, and the following permanent officers elected: *President*—Dr. Joseph Leidy, of Philadelphia. *Vice Presidents*—Dr. Frank Baker, of Washington; Dr. F. D. Weisse, of New York. *Secretary and Treasurer*—Dr. A. H. P. Leuf, of Philadelphia. *Executive Committee*—Dr. Harrison Allen, of Philadelphia; Dr. Burt G. Wilder, of Ithaca, N. Y.; Dr. W. B. Towles, of the University of Virginia; and the President and Secretary, *ex officio.*

Dr. Harrison Allen, of Philadelphia, read a paper on

A BIPARTITE CONDITION OF THE MALAR BONE IN THE NORTH AMERICAN INDIANS,

and exhibited three skulls showing this condition. He said that he had found this bipartite condition always present in Europeans, but had not before demonstrated it in the skulls of native American races.

Dr A. C. Bernays, of St. Louis, presented a paper, illustrated by drawings, entitled

THE DEVELOPMENT OF THE VENTRICULAR VALVES OF THE HEART AND OF THE WALLS OF THE VENTRICLES.

It was shown that the valves were solely the result of the growth of the endothelium in their first and youngest conformation. These were called the primary valves and were analogous in form and structure to the semilunar valves.

Later on these endocardial valves enter into a closer relation with the myocardium. The spongy muscular tissue which first constitutes the entire thickness of the walls of the ventricles grows into a close relation with the primary valves. These latter become smaller and cease to exercise their function, while the muscular tissue takes the place of the endocardial valves. By a change of the muscular tissue into tendinous chords and fibrous layers, the permanent or secondary valve is developed. The primary valves are found attached to the free edges of the full-grown valve in the shape of small nodules, which up to the present time were considered by many anatomists to be pathological formations. These nodules are the rudiments of the primary valves.

It was next shown that in the earliest stages, the ventricular walls of the heart were not supplied with blood from the pericardium, *i.e.*, by the coronary arteries. The nourishment of the walls of the heart originally takes place from within, the blood penetrating into the spongy heart-walls from within. As the outer layers of the walls of the ventricles become more solid, their nutrition cannot be carried on from within, and then the coronary vessels begin to spread from the transverse sulcus, over the surface of the myocardium, and to supply the latter with blood from without.

Finally, the very interesting point was demonstrated, that the primary heart cavity was not the homologon of the heart cavity as we find it in the adult. It was shown that this was due to the process of development of the secondary valves, by which means the primary heart cavity becomes very much enlarged by taking into its compass a large part of the original spongy wall of the ventricle. The author closed by explaining many heretofore imperfectly understood points in the anatomy of the heart, on the basis of the embryological facts above mentioned.

Dr. J. L. Wortman, in behalf of himself and Dr. H. ten Kate, presented a paper upon

THE HYOID BONES OF SOME ANCIENT PUEBLO INDIANS.

The study of the human hyoid arch, in its relation to anthropology, has been hitherto neglected, but that it affords characters of more than ordinary interest and importance in the matter of racial distinction the authors had been led to believe from the results of some recent observations which they had made. Anatomical authorities are by no means in accord in their descriptions of the hyoid bone, especially with reference to the time of life when its various elements unite or co-ossify into a more or less complete bony arch. A review of the works of the German anatomists brought out the fact that they were nearly in accord in the statement that the great cornua of the hyoid bone remain free even in old age. The French anatomists, on the other hand, assert that co ossification of the separate elements of this bone takes place at a comparatively early age. Supposing that the conclusions of these German and French authorities were based upon examinations of the subjects of their respective nationalities, the discrepancy can be accounted for only on the assumption that there is a racial difference in this respect. The English anatomists agree in the main with the French rather than with the German authorities.

The authors of the paper had made a study of a number of hyoid bones, the material consisting of a very complete series of ancient American-Indian skeletons from the Gila and Solado Valleys in Southwestern Arizona. In all they collected ninety-seven hyoid bones, taken from young, adult, old, and very old subjects. From the very old subjects, their great age being indicated by synostosis of the cranial sutures, absorption of the alveolar processes, and more obtuse angle of the lower jaw, there were thirteen bones, and of these union of the great cornua with the body was found in three, the co-ossification existing, however, only on the left side. If the statements of many anatomists can be accepted, the very high percentage of free hyoidean elements found in these ancient peoples (belonging to the pre-Columbian period) distinguishes them markedly from other races. If it is ultimately found that this condition of the hyoid is general in the North American Indians, as well as in some other races, it would be interesting to know in what way, if any, it is associated with language. Since the chief function of the hyoid is the support of the muscles of the tongue, one would be led to infer that in those races where rapid talking and much talking was the rule, the hyoidean elements would co-ossify early, while among those peoples who speak slowly, deliberately, and comparatively little, the hyoidean elements would co-ossify late in life, if at all. The complexity and modification of sounds depending largely upon the use of the tongue would also furnish sufficient reasons for early or late co-ossification.

Dr. Forbes had never seen a perfect union between the body and the greater cornua. A point which might have some possible bearing upon the discrepancy between German and French anatomists in regard to co-ossification of the elements of the hyoid arch was that the Germans are singers while the French are talkers.

Dr. Harrison Allen had noted variations in the cornua of the hyoid, the left horn often being longer than the right, sometimes even pressing against the pharynx.

Dr. Weisse said that the authors of the paper had had the opportunity of examining an unusually large number of specimens. He did not believe that the statements of the individual authorities quoted were founded upon the results of a study of so many hyoid bones. It was a mistake to prepare skeletons without the hyoid bone, yet this was almost invariably done. It would be interesting to compare the condition of the joints of the hyoid bone with those of the costo-chondral articulations.

Dr. Frank Baker said that his experience had led him to believe that the greater cornua were almost always co-ossified in aged negroes.

Dr. Wortman said that the question which remained to be solved was whether there was a difference in different races in regard to the co-ossification of the hyoid elements, or whether the anatomists of one or the other nation were wrong. Do the elements of the hyoid bone co-ossify in old age, or do they not? The speaker was not yet in position to answer this positively, for in the specimens examined by the authors of the paper there were skeletal anomalies leading to the suspicion that the instances noted of co-ossification were themselves anomalies. The questions raised in the paper were interesting to philologists as well as to anthropologists. The speaker hoped to be able to pursue his studies in this direction further.

Dr. A. H. P. Leuf, of Philadelphia, reported a case of

ALMOST TOTAL NON-DECUSSATION OF THE ANTERIOR PYRAMIDS OF THE HUMAN BRAIN.

It was a case of dextral cortical hemorrhage and resulting dextral hemiplegia. Death resulted in a few days, and the conditions of the brain were noted at the autopsy. Only a very slight decussation was perceptible upon wide separation of the anterior median fissure at the bottom of the medulla. The speaker simply desired to put the case on record with those of Brown-Séquard.

Dr. Leuf then read a second paper, and showed nearly one hundred and fifty

DIAGRAMS OF DIFFERENT AREAS OF THE CORTEX

of thirty-seven hemispheres, and also two tables showing the variations from the supposed type of annectant gyri. The Sylvian fissure was little subject to change, only one slight anomaly having been observed in thirty-seven. The fissure of Rolando was often found extending into the great longitudinal fissure and sometimes into it and the Sylvian fissure, but never into the Sylvian fissure alone. The occipito parietal fissure was abnormally long in a number of instances; and in one brain fully one inch deep in either hemisphere. Particular attention was called to the present acceptation of the topography of the parietal lobe. The drawings showed that only a very small percentage had the intraparietal sulcus, but the general rule was an arrangement similar to that of the frontal lobe, *i. e.*, a transverse parietal sulcus running parallel with the Rolandic fissure and a superior and an inferior parietal sulcus, the latter arching over the posterior ascending end of the fissure of Sylvius in the same way that the inferior frontal does over the anterior arm of the Sylvian fissure. The table of annectant gyri also showed a remarkable constancy in deviating from the accepted type, except the first, which was typical most of the time. The study of the brains represented by the diagrams had not been concluded; in fact, it was only begun, and the paper was preliminary to one that was to follow at the next annual meeting.

Dr. George McClellan suggested that photography could be made useful at autopsies in recording the cerebral topography, but Dr. Leuf objected that it would be more expensive and require a longer time than by his method, which consisted in carrying around diagrams of the brain-outline with the three primary fissures *in situ.* These could be modified on the spot while the autopsy was in progress, and the sulci added as required. Similar diagrams for the other areas, like the island of Reil and orbital surface, should also be on hand.

GENERAL SESSION.

Wednesday, September 19th—Second Day.

Dr. Charles K. Mills, of Philadelphia, opened the discussion with a paper (see page 312) on

CEREBRAL LOCALIZATION IN ITS PRACTICAL RELATIONS.

Dr. Roswell Park, of Buffalo, continued the discussion with a paper (see page 310) on

CEREBRAL LOCALIZATION IN ITS SURGICAL RELATIONS.

Dr. David Ferrier said that he took special pride and satisfaction in the fact that this subject had been assigned such an important place in this great gathering of the profession in this country. He had long cherished the idea that the determination of the functions of the brain would in time lead to the successful treatment by surgery of some of the most distressing ailments of our fellow-creatures. When he first broached the possibility of this he received little encouragement, but now cerebral surgery had become a distinct branch of the art of surgery. There is a great future for cerebral surgery. We must, however, be cautious lest we do things which our better judgment and larger experience may not consider altogether justifiable. While there have been many successes, yet there had been some failures. He alluded more particularly to cases of Jacksonian epilepsy. The discharging lesion had been removed in many of these cases without permanent cure. Care must also be taken that in curing one affection we do not induce a greater evil. There is yet much to be learned in regard to the functions of the brain, and in regard to the diagnosis of cerebral disease.

Mr. Victor Horsley described briefly the results of his experiments upon the motor region. He believed that here three functions were clearly represented: 1, the representation of the so-called tactile sense; 2, representation of the so-called motor sense; and 3, the great representation of movement. It is found that, morphologically, the large cells in the fourth layer are concerned in the representation of movement, and he could not understand that we should not allot to the small cells in the upper layer the representation of sensation. He had divided the motor region into minute areas, and studied the effect of irritation of these separate areas. He had found that the representation for any part was not limited to one minute portion of the brain, but that there was a focal point where it was strongest, and then it graduated as we passed outward In his different experiments he had met with certain points of difference. These were attributable to the employment of different species of monkeys. He now uses only the bonnet monkey, and, for all practical surgical purposes, the results are perfectly applicable to man.

Experiments performed during the past summer had enabled him to prove that the convulsions of so-called Jacksonian epilepsy were solely due to the cortex, and not at all dependent upon the spinal cord or upon the bulbar spinal system.

In cerebral surgery we practise simply the ordinary rules of surgery. In cutting out the bone, a one-inch trephine should be first used to determine the thickness of the skull. The surgical engine may then be used to cut almost through the portion of bone to be removed. The bone may then be removed with strong forceps. The dura mater should be first separated. If nothing is found and the operation is an exploratory one, the dura mater should be opened. If we propose to use faradism for the recognition of certain areas, it is important that the ordinary antiseptic solutions should not be applied to the brain, for they tend to prevent the response to the electric current.

Parenchymatous hemorrhage may be prevented by the use of morphia. The ligature must be always applied if possible; never pack the wound. In regard to the recurrence of epilepsy in operations performed for the relief of this affection, he considered that the recurrence was due to incomplete operation. In those cases in which he had removed, to his own satisfaction, not only the lesion, but the surrounding brain-substance for at least one centimetre, there had been no return.

He agreed with the previous speaker, that there was danger of doing too much in certain cases.

Dr. M. Allen Starr, of New York, then discussed the question (see p. 313) of

CEREBRAL LOCALIZATION IN REFERENCE TO APHASIA.

Dr. W. W. Keen, of Philadelphia, compared the head cavity to the other cavities of the body. The brain may be considered to be made up of a number of viscera, having separate and distinct functions, and each of which has its own physical signs and symptoms. While we should be careful not to do too much, we should not err in the other direction. The timidity with which the surgeon formerly approached the abdominal cavity was remarkable; the boldness with which we now attack the lesions of this cavity is almost appalling, and the success equally gratifying. This history will be repeated in the case of the brain.

Dr. Robert F. Weir, of New York, had, since 1883, operated in ten cases of brain surgery. Three times for tumor; three for abscess; twice for hemorrhage into the cerebrum where there was no external injury to indicate its locality; once for epilepsy; and once for cerebral pain. In the last case the tumor was so deep that there was nothing to indicate its presence after the brain was exposed. It was one and a half inch below the surface. The growth proved to be a sarcoma. The operation was done last November. The patient is still living, but there are signs of a recurrence of the growth.

Bergmann says that operation should not be performed when the patient is in a coma, or when the tumor is large. Dr. Keen has removed a tumor weighing over four ounces, with recovery, and Mr. Horsley has removed with success a tumor weighing four and a half ounces from a patient in a state of coma. Sometimes, although no tumor is found, the operation causes disappearance of the symptoms by relieving the pressure. This might be applicable in apoplectic hemorrhage where the clot could not be removed.

He said he had gone over the brain to find what parts are accessible to surgical interference. We are able to strip up the longitudinal and lateral sinuses to a considerable extent. The dura mater may be separated for a considerable distance from the bone. He had been able to raise up the frontal lobes so as to see the anterior clinoid processes, and he had been able to feel the foramen magnum.

ASSOCIATION OF AMERICAN PHYSICIANS.

Wednesday, September 19th—Second Day.

Dr. Robert T. Edes, of Washington, read a paper on

THE ABSOLUTE AND RELATIVE VALUE OF ALBUMIN AND CASTS, AND OF RENAL INADEQUACY, IN THE DIAGNOSIS AND PROGNOSIS OF DISEASES OF THE KIDNEY.

The term albuminuria has held a place in medical nomenclature, until comparatively recently, synonymous with Bright's disease. The writer referred to recent and most extensive observations on albuminuria. The varieties of albumin were then considered. Dr. Munn's observations were cited to show that many cases of intermittent albuminuria, when followed out carefully, are found to have developed Bright's disease. Four of Dr. Munn's sixty-nine cases died within three years. Many such are met with in business men of middle-life, and of overweight. The great diagnostic significance of casts, and their variety, was next touched upon. A question of great interest is, whether we can detect a pathological condition of the kidney in the diminution of any of the constituents of the urine. Dr. Noyes' paper in the *American Journal of the Medical Sciences* is of interest in this connection. Long after the presence of kidney disease is established, the daily quantity of urea excreted may be far above the physiological limit. A very badly damaged kidney may, in fact, get rid of a large quantity of urea. Cases in illustration of the fact that the excretion of urea and other solids does not necessarily fall below the physiological limit. The question of food is here of the greatest importance. In conclusion, numerous tables of statistics, bearing upon the question of albuminuria and the secretion of urea, were presented.

Dr. Janeway followed with a paper on the same subject. If we consider first the diagnostic importance of albumin, we are forced to state that, from various circumstances, it is apt to be overrated, and, taken by itself, to be by its presence, or its absence, extremely misleading. Particularly is this true of examinations of single samples of urine, or even of one, or of several days' urine, provided such days are not close together, or, on the other hand, sufficiently separate. Cyclical, or intermittent, or functional albuminuria is the most interesting of the possibilities. In these cases, the albumin being generally present in the daytime and absent at night, is apt to be overlooked by those who examine only the night and morning urine, and detected by those who examine urine passed in their presence, as at the time of an office visit, or in examination for life insurance, or by those making a study of the urine of a large number of individuals. Mistakes are especially liable to occur between this form and those cases of chronic diffuse nephritis which are attended by the intermittent appearance of albumin. An occasional occurrence of a hyaline cast cannot be considered as proof of chronic renal disease, as against cyclic albuminuria. Such casts the writer has seen occur in two cases at considerable intervals, the urine not having shown them at a number of previous nor subsequent examinations. So, too, while ordinarily the percentage of albumin is small, yet in some instances it is large, in one case under the writer's observation reaching twenty-five per cent. by bulk, moist. Neither do the age limits usually set always hold. In one instance functional albuminuria was observed in a child of five years. The varieties of casts were touched upon, and the liabilities to error in microscopical examination pointed out. The paper abounded in brief references to cases illustrative of points made.

Dr. James Tyson, of Philadelphia, presented a communication entitled,

THE RELATION OF ALBUMINURIA TO LIFE INSURANCE.

No system of life insurance is perfect which does not include those who are apparently healthy and those who are not. Certain applicants presenting themselves for examination for life insurance are wrongfully rejected, because of the presence of albumin in the urine. After this introduction the writer went on to mention the different terms used to indicate the particular forms of albuminuria under consideration, and gave his decided preference to the term "functional." Two illustrative cases, which he considers "safe risks" for life insurance companies, were presented. One of the histories was that of a young man, who had been under the observation of many physicians, among them Dr. Stewart, of Edinburgh, the various observations extending over several years. The other, a less favorable family history, and an older man. In both there was final disappearance of albumin. Dr. Tyson went on to sketch the conditions which if observed by competent and well-trained observers, if it were always possible to get such, would enable the companies to save these risks. These are: 1. The applicant must in all other respects present the signs of good health. 2. The albuminuria must be unaccompanied by tube-casts, however perfect may be the health in other respects; albumin and tube-casts conjoined always meaning structural changes. 3. The specific gravity of the urine, that is, the "real" specific gravity (that of the quantity for the twenty-four hours), should not be lower than 1.015–1.025. Great care must be taken to secure the "real" specific gravity, as it would be unfair, to reject the candidate on account of the specific gravity of a single specimen. 4. The signs of hypertrophy of the left ventricle, and the existence of high vascular tension associated with albumin, would exclude the candidate. 5. The age of the applicant is a highly important consideration. It is doubtful whether any person forty years of age with functional albuminuria should be accepted, unless at least he has been long under the observation of a competent and conscientious examiner. 6. The presence of true gout in any case should decide against the person, because gout is always, sooner or later, followed by interstitial nephritis. Finally, retinal changes such as are associated with nephritis, should exclude the applicant. In conclusion, the writer does not claim, of course, that we are in a position to put these conditions in operation, but believes, as we are enabled gradually to secure the desired education and training in medical examiners, the applications of these conditions will be possible. The absence of the albumin from the urine passed on rising in the morning is an important aid in the diagnosis of functional albuminuria, but not an essential one.

Dr. Jacobi opened the discussion on the papers by remarking that, to criticise three papers of such excellence would be impossible, but he would remind the members of the Association of an anatomical fact, which is an explanation of the presence of albumin in the urine of children. There is, at the very beginning of their existence, a discrepancy between the growth of the renal arteries and the growth of the tissue of the kidney. Besides, the capillaries of the kidneys do not permit of the passage of the same quantity of water through them as in adults. Thus there is disproportion.

Dr. Pye-Smith, of London, preferred the term "functional" to any of the other names given to this condition. At the present day there is no physiological ground for believing that the healthy kidney secretes albumin at all. With respect to the tests for albumin, he stated that he had come back to the old test of heat and nitric acid, in suitable proportions. Many of the tests are too delicate and of no practical importance. In insurance cases it does not answer to be too minute or individual. The question of life is not as regards A, B, or C, but whether a hundred persons are likely to live beyond the average period.

Dr. A. L. Loomis, of New York, followed with a paper on

THE CARDIAC CHANGES IN CHRONIC BRIGHT'S DISEASE.

Pathological processes become physiological in that they tend to the preservation of health and the prolongation of life. So long as full nutrition is maintained in the heart, it meets every obstacle to its action with added force. Dr. Loomis then went on to consider that it is a failing and a hypertrophied heart which is to be found in Bright's disease, as in other diseases. Authorities discuss a hypertrophied heart as though of the utmost importance, and make little or no reference to cardiac degeneration in its relation to the cardio-vascular changes in chronic Bright's disease. The writer then reviewed the literature of the subject and the different theories advanced in regard to the cardiac and vascular changes in Bright's disease. He then briefly stated Cohnheim's theory, namely, that the circulation in the kidney, as in all other glands, varies with the demand upon their functional activity. Circulation through the kidney varies directly with the proportion of the parenchymatous elements of the kidney and the excrementitious elements in the blood. Any diminution in the glandular tissue of the kidney at once raises the ratio between the excrementitious materials and the functional powers of the kidney. As a result, when the renal functioning power is lessened in connection with retention of excrementitious materials, the systemic forces generally are projected upon the kidney, in order that the total elimination may remain undiminished.

We thus have two widely different conditions tending to produce arterial tension—conditions which may act singly or conjointly—and affording a rational explanation of the varying amount of cardiac hypertrophy found in apparently similar renal conditions. *First*, a general and primary arterial sclerosis to which both the cardiac and renal changes are secondary; and, *second*, arterial as well as cardiac hypertrophy, which are compensatory and conservative as is cardiac hypertrophy in aortic lesions.

In summing up authorities, while most of the theories as well as clinical evidence thus adduced seem to be directed to establishing a cause for the arterial change and increased tension, it was claimed that many of the facts presented support this proposition, that degeneration of the heart-walls with dilatation of the heart-cavities are the most frequent, and perhaps the characteristic, cardiac changes in chronic Bright's disease. He then presented observations made in a series of cases, typical of the different varieties of kidney and cardiac changes which are found associated in chronic Bright's disease. In connection with these he presented tables in which were arranged, in tabulated form, the renal, cardiac, and vascular changes which were found at the autopsies of forty cases of chronic Bright's disease. In a general review of the cases presented, he reached the following conclusions: As a rule, the more extensive the obliterating changes in the renal arterioles, the greater the degree of cardiac hypertrophy. In two cases where the cardiac hypertrophy was greatest, the only change found in the kidneys was obliterating arteritis in the arterioles. In other varieties of Bright's disease the heart-changes seem to be directly dependent upon the renal disease, or rather upon the toxæmia and faulty nutrition which result from them. In all cases of chronic Bright's disease increased arterial tension and compensatory hypertrophy are present some time during their course. But when the time is reached at which the renal symptoms clearly establish an interference with the function of the kidney, a feeble heart-action and diminished arterial tension will indicate degenerative cardiac changes. The table gave no evidence of acute endocarditis, secondary to renal disease. But chronic endocarditis was present in seven cases. Where a systolic murmur was heard during life, accompanying sudden cardiac dilatation, the autopsy gave no evidence of mitral disease. That rheumatic valvular disease may remain latent for many years, but when Bright's disease is developed in such cases heart insufficiency is immediately developed. His cases gave no evidence that valvular lesions occurred secondary to kidney disease. He presented the statistics of Bellevue and Roosevelt Hospitals, showing that in a total of 164 cases, 43 were complicated by Bright's disease secondary to the valvular disease. The result of the studies seems to indicate that the cardiac changes in chronic Bright's disease have a wide range of variation, and that we cannot predict with certainty the exact nature of the changes which may be present in any given case, except that possibly they are degenerative, and that sooner or later a condition of heart-failure will be reached which may fairly be designated as a Bright's heart. The more marked these are in any case, the more unfavorable the prognosis. We must, as it seems to me, regard Bright's disease as a constitutional disease, in which the repair and waste in all the tissues of the body are imperfectly carried on, and in one way or another the kidney changes are expressive of other visceral and arterial changes, which, combined with the kidney lesion, make up the clinical and pathological history of the disease.

Dr. Delafield, in discussing the paper, objected to two of the propositions advanced by Dr. Loomis, as counter to his experience: 1st, the proposition that cardiac hypertrophy is often developed without any change in the kidney, except in its arterioles; 2d, that the morbid changes in the glandular structure of the kidney are usually associated with changes in the cardiac walls.

Dr. Peabody spoke of the frequency with which the heart is not hypertrophied in well-marked cases of chronic diffuse nephritis. His remarks were based upon a study of two thousand consecutive autopsies performed at the New York Hospital. Perhaps in thirty per cent. of the cases no hypertrophy of the heart had been noticed.

Dr. Samuel C. Chew, of Baltimore, Md., followed with a paper on

THE RELATION BETWEEN CHRONIC INTERSTITIAL NEPHRITIS AND ANGINA PECTORIS.

After stating that there was no systematic account of the relations between the diseases to be found in any of the writers on the subject, he proceeded to consider the question chiefly from a clinical point of view.

Dr. Da Costa, of Philadelphia, Pa., presented a paper on

THE TREATMENT OF VALVULAR AFFECTIONS OF THE HEART.

He began with a reference to the prevailing ideas on the treatment of these affections. The presence of a valvular affection is not the key-note to be taken. The indications on which the true treatment should be based are: 1, The state of the heart-muscle and heart-cavities; 2, the rhythm of the heart; 3, the condition of the arteries and veins of the body; 4, probable length of disease; 5, the general health of the patient; 6, the secondary results of cardiac affection. The writer gave detailed statements in regard to the medicinal treatment of the various forms of heart complaint. The question of the causes of valve disease was considered. The futility of treating valvular disease, the result of rheumatism, after the acute stage of the fever had passed, was pointed out. The treatment of atheromatous disease was also unsuccessful. There is one form of disease in which the happiest results are obtained in treatment, namely, that form called by the author functional valvular disease. Of Oertel's method of treatment he has had no experience. He presented two cases to show how long and how continuously some may take nitro-glycerine. In conclusion, he called attention to the necessity of making periodical examinations of patients affected with heart disease.

Dr. G. Baumgarten, of St. Louis, Mo., read a paper on the

DISTURBANCES OF THE HEART-RHYTHM WITH REFERENCE TO THEIR CAUSATION AND THEIR VALUE IN DIAGNOSIS.

By itself, the condition of irregularity of the heart-rhythm may be considered to be of no great significance, but it is far otherwise when taken in connection with other things. It is desirable to group cases according to the forms of irregularity. These are: 1, mere fluctuation variations; 2, variations in frequency as well as in amplitude; 3, comprises all cases of intermittent, deficient, alternating, and bigeminous rhythm. The condition producing arhythmia of the heart are: 1, affection of cardiac centres in the medulla; 2, reflex influences; 3, the action of drugs on the nervous apparatus of the heart; 4, changes in the heart itself (this class constitutes the majority of the cases); 5, deficient blood-supply; 6, dilatation from heart strain. The condition is more likely to arise in insufficiency than in stenosis of the valve. In sclerosis of the coronary arteries we also have a condition producing a-rhythmia. In conclusion, the writer briefly touched upon the diagnostic value of the various forms of a-rhythmia.

Dr. James K. Thacher read the final paper of the meeting, on "The Treatment of Valvular Affections of the Heart."

AMERICAN SURGICAL ASSOCIATION.

WEDNESDAY, SEPTEMBER 19TH—SECOND DAY.

Dr. Hunter McGuire, of Richmond, Va., read a paper on

THE FORMATION OF AN ARTIFICIAL URETHRA FOR PROSTATIC OBSTRUCTION.

It has been my lot to meet with a number of cases of hypertrophy of the prostate gland, which produce more or less obstruction to the passage of urine. These are conveniently divided into three classes.

1. Cases where the obstruction was due to temporary congestion of an already enlarged gland, which yielded to the ordinary treatment and did not return.
2. A class of cases when the obstruction to the passage of urine was permanent but not great. Attention to the general health, the occasional introduction of the catheter and washing out the bladder were all that the cases required. These cases are, however, never free from danger from exposure, etc., and gradual enlargement may go on and bring about the condition met with in the third class.
3. In these cases the obstruction is great and fixed; micturition is frequent and difficult, perhaps impossible without the aid of the catheter. The introduction of the instrument grows more and more difficult. Offensive residual urine is always present, and the general health suffers greatly. Cystitis, localized or general, is a painful and pronounced symptom. Violent tenesmus of the bladder, provoked by the obstruction, injures the vesical ends of the ureters, possibly a reflux of stale urine is driven into these canals, and ureteritis follows, then pyelitis and pyelonephrosis, from which the patient dies.

The paper was devoted to a consideration of surgical interference in this third class of cases.

In one of the cases of stricture in a man aged sixty-five, the patient had, two years before coming under observation, a second cause of obstruction. A well-organized stricture was found in membranous portion of urethra. Prostate was enlarged, more marked on the left side. Urine showed no evidence of renal disease. An oxalate calculus, three-fourths of an inch in diameter, was also recognized. The high operation for stone was performed. The bladder-walls were found thick, and unyielding, and contracted. The left side of the gland jutted into the bladder one and one-half inches further than the right side. The middle lobe was of the size of the thumb, and almost completely closed the urethra. It was decided to retain a fistulous opening through which urination could take place. This tract was two and one-half inches long, and extended upward and forward. In its passive state it was closed by the pressure of the parts through which it passed. When the bladder became full and contracted, the urine was forced through the fistulous tract. He can now retain water for two or three hours, and has voluntary power both to retain and expel urine.

Case II. was a man aged sixty-nine, who had been cut for stone in 1881. In 1883 I found the prostate enlarged and cystitis present. He was given a gum catheter, and shown how to use it. In 1886 electrolysis was employed without success in trying to reduce the size of the prostate. July 4, 1888, an operation similar to that performed in the first case was done with equally good results. At times he is able to retain urine for six hours. He never has any desire to empty the bladder, no matter how full the organ is.

Dr. John H. Packard, of Philadelphia, read a paper on

SUPRA-PUBIC CYSTOTOMY.

The present paper was supplementary to one on the same subject read by Dr. Packard at the last meeting, and was intended to correct an accidental omission of the views of Sir Henry Thompson. These were now considered, extensive quotations from the works of this author being given. Two cases were reported, in one of which the operation was performed for the removal of a portion of a silver catheter broken off in the bladder; and in the other, for the removal of a piece of rubber catheter, said to have been broken off several months previously. In this case, a stone weighing five hundred and seventy-one grains was removed, in the interior of which was found the *foreign body*.

Dr. S. W. Gross, of Philadelphia, thought that Dr. McGuire was to be congratulated on having introduced a new operation, based upon the mechanism of the bladder, and the physiology of micturition—the formation of an artificial urethra in a new position. The various operations which had been performed for the relief of prostatic obstruction were next referred to, the operations of Harrison, Mercier, Bartinini, and McGill being considered.

Dr. William T. Briggs, of Nashville, thought that perhaps in the cases reported by Dr. McGuire, a better result might have been obtained by lateral lithotomy, provided the stone were not too large to be removed by that route, for he had noted that after incision into the prostate, the gland diminished in size.

Mr. Reginald Harrison, of Liverpool, said that there are two general methods of relieving obstruction due to enlarged prostate, one by attacking the gland through the bladder, and the other through the perineum. In his operation he makes a median or lateral incision through the perineum according to circumstances. The obstructing prostate is next divided with considerable freedom, and a drainage-tube of considerable size introduced. From this operation he gets good results. Perineal lithotomy is preferable to the supra-pubic operation, because the lateral incision gives sufficient room for all manipulations. It gives an ample opening for the removal of a stone of considerable dimensions. It also permits of the more or less permanent drainage which these cases require. He had also, through a perineal opening, used the perineal lithotrite with success. All methods of operation should be remembered, and each employed in those cases where it seems indicated.

Professor Thomas Annandale, of Edinburgh, had come to the conclusion that if an operation is to be performed for the relief of prostatic obstruction, the perineal operation is the best. This allows of examination of the bladder, permits drainage, and probably causes a diminution of the hypertrophy. It enables you to occasionally remove a portion of the enlarged prostate when this assumes a pedunculated form. The speaker exhibited a rubber tube which he had found useful in cases of Harrison's operation when a permanent tube is required.

Dr. A. Vander Veer, of Albany, said that the testimony presented in his paper last year was in favor of the perineal opening so far as drainage was concerned. He had employed Harrison's operation in a number of cases and the results had been such as to impress him favorably.

Mr. Arthur Durham, of London, emphatically endorsed what had been said in regard to operation of stone, that no one operation is applicable to all cases. It is a great mistake to be men of one method, especially in surgery. When we hear a man say that he treats all his cases of fracture in such a way, all his cases of stone in such a way, and all his cases of prostatic disease in such a way, we may be sure that such a man has a very small practice and experience or else is a very great fool. In cases in which stone in the bladder is complicated with enlarged prostate, the perineal incision seems to me to be better than the supra-pubic.

PROFESSOR HINGSTON, of Montreal, believed that the supra-pubic operation was one to be performed only in exceptional cases. These he classified as follows: 1. In those cases of stricture in which the obstruction cannot be overcome in time to relieve the patient of great suffering. 2. In cases of prostatic obstruction. 3. In cases of tumors of the bladder which would interfere with the lateral operation. 4. In cases where the stone is too hard or too large to be removed either by lithotrity or by lateral lithotomy. He had himself removed, without injury to the soft parts, a stone weighing five ounces and five drachms.

Sir WILLIAM MACCORMAC, of London, had performed the operation of supra-cystotomy occ sionally. He had never seen any untoward consequences, and the operation seems to be devoid of all risk. He did not consider that drainage was necessary after this operation. The bladder empties itself freely and the drainage-tube is a source of irritation.

THE PRESIDENT, DR. D. HAYES AGNEW, being called upon, said the ground had been so thoroughly covered that there was little to be added. He agreed with those who held that no single operation was applicable to all cases. The supra-pubic operation may be appropriate in certain cases, while in others the perineal operation is the proper one. In order to avoid the unpleasant consequences which occasionally follow the perineal operation in children, where the prostate is small, I avoid the introduction of the finger into the bladder, and remove the stone with forceps not much larger than the staff.

While there may be no danger in the supra-pubic operation in skilled hands, yet with the inexperienced operator there will be risk of opening the peritoneal cavity. He thought that a number of cases had been reported of rupture of the bladder following injection of the organ after dilatation of the rectum with the rubber-bag.

A paper entitled, "Forty Years of Chloroform and Ether in Louisville, Ky.," by DR. D. W. YANDELL, of Louisville, Ky., was read by title.

The following are the officers of the Association for the following year: *President*, Dr. D. W. Cheever, of Boston; *Vice-Presidents*, Dr. T. W. Richardson, of New Orleans, and Dr. John B. Roberts, of Philadelphia; *Secretary*, Dr. J. R. Weist, Richmond, Ind.; *Treasurer*, Dr. P. S. Conner, of Cincinnati; *Recorder*, Dr. J. Ewing Mears, of Philadelphia; *Additional Members of Council*, Dr. W. F. Peck, of Davenport, and Dr. S. W. Gross, of Philadelphia.

The next meeting to be held beginning the second Tuesday in May, 1889, at Washington. Chairman of Committee of Arrangements, Dr. J. S. Billings; Member of Committee of Arrangements, Dr. J. Ford Thompson, of Washington.

DR. WILLIAM T. BULL, of New York, presented a communication on

THE SURGICAL MANAGEMENT OF TYPHLITIS AND PERITYPHLITIS.

A brief report of the cases operated upon was given and the following conclusions presented:

Our present knowledge justifies the statement that both the cæcum and appendix may be the starting point of an inflammation spreading to the peritoneum or to the peritoneum and cellular tissue of the iliac fossa, constituting a complicated lesion which, for convenience' sake, we may call "perityphlitis."

This may be in its clinical course resolving or suppurative, each marked by definite symptoms in some cases; in others difficult to recognize.

Needle exploration is a justifiable and desirable method of diagnosis, though attended by some risks. These may be reduced to a minimum if care be taken to reserve the practice for cases where the symptoms have lasted several days and where a distinct indication-"tumor" can be made out.

Suppurative perityphlitis may be a spreading or limited (circumscribed) perityphlitis. Both begin with the same set of symptoms, and it is important to discriminate between them in the first twenty-four or forty-eight hours, or even on the third day.

The presence of any of the local or constitutional signs of general peritonitis, justifies the diagnosis of a spreading or generalization, and calls for the performance of laparotomy and the repair of the lesions found.

The absence of these signs, or their strict localization, warrants delay of a varying length. Any time after a week the abscess may be opened by an incision which must reach the pus, whether it be extra- or intra-peritoneal.

In doubtful cases the risk of the operation is less than the risk of the disease.

The propriety of exploring and removing the appendix in recurring cases must still remain *sub judice*.

DR. J. EWING MEARS, of Philadelphia, read a paper on

THE PROPRIETY OF SURGICAL INTERFERENCE IN PERFORATING TYPHOID ULCER.

The present state of our knowledge and our largely accumulated experience, have enabled us to define with a degree of exactness the limits of surgical interference in certain affections of the abdominal organs. The researches of Senn have shown that complete extirpation of the pancreas is invariably followed by death, while partial excision is a feasible operation. We are also able to define the limits of operations in affections of the spleen and kidneys. We may venture to approach the discussion of operative interference in perforating typhoid ulcer with the feeling that here we may be compelled to define a limit to the employment of surgical measures, not without regret at our inability to overcome the barriers which oppose success, but with a desire to maintain always the good repute of surgical science and art.

A clear distinction must be made between the widely different conditions which precede and follow perforation in typhoid ulcer and in ulcerations of the intestinal canal due to other causes. In typhoid fever, in addition to the intestinal lesions, there is a general degenerative process involving all the important organs. In traumatism the general condition of the patient may be good. In inflammatory conditions, while the general system may be profoundly impressed, the lesion may be regarded as local in its nature. In diseases of a chronic character, the system has accommodated itself to the impression made by the morbid affection, and the degenerative changes which may occur are not usually general in character.

A careful search of current medical literature reveals but four cases of surgical interference in perforating typhoid ulcer, in all of which a fatal result occurred. The reports of these four cases were given in detail.

The following propositions and suggestions were offered:

1. Surgical interference is not justifiable and should not be instituted in cases of typhoid fever, in which perforation occurs when the infection process is at its height.

2. In mild cases of the disease in which the pyrexia has not been of high grade, and in which perforation occurs at the end of the third week, or later, when the stage of convalescence is fully pronounced, laparotomy may be performed. Surgical interference in cases of this character is advocated with the hope that, if the method of operation suggested by Lücke—laparotomy

with the creation of an artificial anus—be adhered to, success may be attained.

3. Rapidity of operation will be an essential factor in the achievement of success—through which prolonged exposure of the cavity will be avoided and shock greatly lessened.

Dr. B. A. Watson, of Jersey City, said that in cases where perforation has occurred, the sooner operation is performed the better. He considered that it is safer to make an exploratory incision than to use the needle.

In regard to the paper of Dr. Mears, it covered the ground completely. In those severe cases of typhoid fever where perforation occurs and life is about ebbing away, it would be folly to resort to operation, but in mild cases where perforation occurs the operation should be done early.

Dr. R. B. Bontecou, of Troy, N. Y., had performed the operation in one case of perforation in the third week of typhoid fever; the patient, however, died. He thought that it would succeed in some cases, as in those in which perforation follows imprudence during convalescence.

Dr. O. B. Nancrede, of Philadelphia, thought that the proper place for incision was two inches to the right of the anterior superior iliac spine. He had operated in two cases; in the first there was no pus, but three or four perforations were found; this patient recovered. The second case was that of a child operated on four days ago. The patient had done well since the operation.

Dr. Gordon, of Portland, referred to the absence of symptoms met with in these cases, and cited a case in which the symptoms were not distinct, but in which a pint of pus was found, with general peritonitis and perforation of the appendix. In this case an incision on the right side would not have reached the pus.

Dr. D. W. Cheever, of Boston, reported a case in which strangulation of an old hernia occurred in the third week of typhoid fever, the patient not being seriously ill. A simple incision through the sac was made and the bowel replaced, but the patient did not rally from the shock.

Dr. W. H. Carmalt, of New Haven, referred to a case which had come under his observation with symptoms of internal obstruction. Operation was suggested but refused. The patient died, and the autopsy showed perforation of the appendix and extravasation of fecal matter. The appendix was attached deep down in the pelvis, where there was a small collection of pus. This was reached only with the greatest difficulty, and after turning the intestine out of the abdominal cavity. This abscess was inaccessible to any of the ordinary methods of operation. The careful exploration of the rectum in this case failed to reveal any sign of disease.

Dr. Joseph Ransohoff, of Cincinnati, thought that the general impression that perityphlitis is necessarily associated with perforation, was an error. There are two classes of cases. In one there is a distinct tumor, which in these early operation is by no means indicated. In these cases adhesions have formed and there is a natural tendency to cure. In these cases the abscess finally perforates the abdominal wall, or is relieved by incision. The second class is that in which the symptoms of perforation develop suddenly. In these cases the incision should be median.

Dr. T. F. Prewitt, of St. Louis, thought that there must be many cases of inflammation in the region of the cæcum that never suppurate. He recalled a number of these cases, only two of which had died, one from perforation and the other, an old man, from exhaustion incident to an intestinal affection. In almost all of these cases the patients had had three or four previous attacks.

Dr. Reginald H. Fitz, of Boston, held that the appendix was the seat of disease in the great majority of cases. The symptoms usually enabled the physician to make a correct diagnosis. The use of the exploring needle was not considered advisable. The cæcum can always be readily found by remembering that it is attached to the colon.

Dr. George W. Gay, of Boston, remarked that in the cases on which he had operated recovery had followed in those cases in which offensive pus had been evacuated, while in those where he had found only serum and flakes of lymph a fatal result followed operation.

Dr. J. H. Packard, of Philadelphia, read a paper entitled

SIMULTANEOUS LIGATION OF THE RIGHT CAROTID AND SUBCLAVIAN ARTERIES FOR ANEURISM OF THE INNOMINATE.

The symptoms of aneurism followed a blow upon the chest. The patient died three days after the operation with symptoms of suffocation. No autopsy could be obtained.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Wednesday, September 19th—Second Day.

Dr. Potter, of Buffalo, read a paper on

DOUBLE OVARIOTOMY DURING PREGNANCY—A SUCCESSFUL CASE GOING ON TO FULL TERM.

He related the various incidents of the case, which, however, terminated favorably.

Dr. Vander Veer had had some cases of single ovariotomy during pregnancy, and he thought the operation thoroughly justifiable.

Dr. Montgomery had had a successful similar case. He pointed out that these cases showed that the ovaries have nothing to do with bringing on labor.

Dr. Maxwell, of Keokuk, remarked that Dr. Potter's case had nursed her child, showing that the ovaries have nothing to do with lactation.

Dr. Byron Stanton, of Cincinnati, read a paper on

INDUCED LABOR.

He held that the operation was far less serious than other operations, such as Cæsarean section, and the death-rate to mother and child was diminishing steadily. Diameters of three and a half and two and a half inches are small enough to demand interference. In placenta prævia it was, he thought, better to induce labor, because we would then have to deal with a woman who was not exhausted with hemorrhage. He urged it strongly in albuminuria of pregnancy. He was not so much in favor of it in vomiting of pregnancy. There are three methods of inducing labor, viz.: By medicines acting through the general system, such as ergot, which he condemned; sympathetic methods, such as irritating the breasts; and methods applied directly to the uterus, such as galvanism, doubtful. Tampons to the cervix are useful in placenta prævia; hot-water injections to the vagina, but they are uncertain; tents and Barnes' bags, good; injection of water between the membrane and the uterus; but the best method is the introduction of an elastic bougie which is left in the uterus.

Dr. Opie, of Baltimore, strongly urged interference in albuminuria of pregnancy.

Dr. A. L. Smith, of Montreal, strongly urged interference in uncontrollable vomiting of pregnancy, and he related a case where the patient was at the point of death, and where the operation was followed by immediate recovery.

Dr. Clarke, of Cambridge, advocated the use of an aseptic bougie where there was not urgency.

Dr. Price said that ergot was nearly always followed by laceration of the cervix and perineum.

Dr. Opie, of Baltimore, read a paper on

THE INDICATIONS FOR ARTIFICIAL AID IN LABOR.

He thought the traction-rod forceps alone should be used in the high operation, but never at the inferior strait. All forceps may be divided into high and low forceps; he deprecated the name of the inventor being attached to the instruments. He urged going slowly, rather to follow and help nature, than supplanting her. He pleaded for judiciousness in their use. Forceps were rarely required in the first stage, in which laceration would almost surely follow. To use the forceps for the purpose of curtailing the pains of labor is a very doubtful proceeding. It would be better to use anodynes. Some operators only use the forceps once in three thousand labors, while others have used them once in every three labors. The best rate would seem to be one in sixteen. The reader's rate has been one in ten in private practice, and he felt that he had used them too often.

Dr. Price wished to express his approval of the views enunciated by Dr. Opie.

Dr. Stewart, of Philadelphia, thought that their use had been greatly abused; rarely, if ever, should they be used in the first stage. He presented a pair of forceps with parallel instead of crossed bars.

Dr. Townsend, of Albany, said that the first stage of labor was under the influence of the sympathetic; while the second stage is under the influence of the cerebro-spinal system.

Dr. Clarke, thought that the forceps were sometimes of great advantage when the head was delayed at the superior strait.

Dr. Etheridge, of Chicago, read a paper on the

TECHNIQUE OF VAGINAL HYSTERECTOMY.

Bowels and bladder should be well evacuated, and antiseptic douches for twenty-four hours previously, and a very hot one immediately prior to operation. His method is especially noticeable for his substituting forceps pressure for ligatures, thus reducing the time required for the operation to as little as seven minutes.

Dr. Montgomery highly approved of forceps or clamps for the broad ligaments, as the later are apt to shrink after being tied.

Dr. Vander Veer said the operation was a most desirable one. It was greatly employed by Pean of Paris.

Dr. Burns, of Pittsburg, said he had seen Fritz, of Breslau, perform the operation, using sutures.

Dr. Sharpe, of Chicago, related a case of

INTRAPERITONEAL HEMATOCELE WITH SUPPURATION.

He attributed the suppuration to the use of the aspirator as a means of diagnosis. He performed laparotomy, and removed over a gallon of pus, the patient soon making a good recovery.

AMERICAN GYNECOLOGICAL SOCIETY.

Wednesday, September 19th—Second Day.

Sir Spencer Wells, of London, read a very brief paper entitled

SECOND OVARIOTOMY ON THE SAME PATIENT.

In operating on a young woman in whom he was uncertain whether the other ovary was sound and healthy or not, he has sometimes removed the other ovary and sometimes not. In some cases he had left apparently slightly diseased ovaries in young women, and they have borne children and did not die. The removal of the second ovary does increase to a slight extent the danger of the operation. He always left the other ovary if truly healthy, and removed it if positively diseased. In old women, where the ovary is useless, he was more free to remove the second than in young women who may yet bear children. In one thousand ovariotomies he left the second ovary in a number of women, and these women bore two hundred and twenty-eight children, and only two of the women died. If these second ovaries had been removed these two hundred and twenty-eight children would not have been born.

The paper was discussed by Drs. Thomas, Kelley, and Goodell.

Dr. William Thompson Lusk, of New York, read a paper entitled

THE NEW CÆSAREAN SECTION.

The operation of Sanger has grown wonderfully in Germany and elsewhere. He reported at length his three cases of Sanger operation in Bellevue Hospital, New York, during the past year. The first case was on account of carcinoma of the whole vagina, bladder, and rectum. Craniotomy was out of the question, and as there was too much new-growth, which would be naturally torn away, the operation was done for the child. In the third case the decidua was found in a necrosed condition. It was removed with great care with the fingers, and the uterus washed out. Two babies lived, and the third died in thirty-six hours of trismus. Mothers all lived. He dwelt at length on the importance of studying the indications for the operation. The doctor went thoroughly into the literature and the statistics. Fair treatment of those placed in our charge demands that the comparative dangers of craniotomy and Cæsarean section be placed before the patient and friends, and that they be allowed to decide. The recoveries in this country, not quite forty per cent., are inclined to

PARALYZE THE OPERATOR.

It is a quite important precaution, just before the operation, to know that the fœtus is alive by auscultation. Leopold recommends catgut of a good quality for both general and deep sutures, as this produces less irritation. If a case is operated on after the Sanger method, the surroundings are good, and the nursing is of the proper character, the operation is a credit to Sanger. If the case is one from the country, or in bad hygienic surroundings in private practice, nursing inferior, and probably in the charge of careless, ignorant, and superstitious hands, the operation may be a Sanger, but the recovery is a miracle.

Dr. Howard A. Kelley, of Philadelphia, reported one case in which the child rallied but died of trismus in thirty-six hours. He also reported one other case.

Dr. Henry J. Garrigues, of New York, had performed Cæsarean section twice. He thought that Cæsarean section required much more assistance than craniotomy, and hence sometimes in private practice, especially in the country, should be preferred on this account. If catgut is used we must use a particular kind. The common is unreliable. He agreed with Dr. Lusk on the great importance of turning out the uterus. His first operation is put down as the third operation by the Sanger method; at the time of this operation he did not know that there was such a man as Sanger. He had never read a line of his work. Afterward he heard of him, but could not get his book in New York, and had to send to Germany for it. In his book of two hundred pages there is only one original suggestion, that we cut out some of the muscle before suturing. Sanger has done excellent library work.

Dr. G. J. Englemann, of St. Louis, thought the craniotomy patient generally in a much poorer condition for operation than the Cæsarean patient.

Dr. Polk, of New York, reported two Sanger operations.
